

Mathematics in Motion

A Friendly Guide to Mathematical Theories

A survey with worked examples and routes for further study

A popular science introduction

The big picture

Mathematics is a collection of ways to understand patterns. One theory may study patterns in numbers, another in shapes, another in change, and another in the way objects are connected. The theories have different names because they ask different kinds of questions, but they share one habit: simplify a situation, find the important pattern, and use that pattern to make a prediction or a decision.

Here is the map of this book:

Numbers	Number theory studies whole numbers and primes. Algebra studies rules for combining objects and the symmetries of those rules.
Shapes	Geometry studies measurements such as length and angle. Topology studies broader features such as connected pieces and holes.
Change	Calculus and dynamical systems describe motion, growth, waves, stability, and sudden changes.
Uncertainty	Probability describes chance. Statistics uses observations to learn what is likely to be true.
Connections	Graph theory studies networks. Game, queue, and control theories study decisions, waiting, and feedback in those networks.
Messages and machines	Information and coding theories explain data, noise, and reliable communication. Automata and computation theory explain what machines can recognize or calculate.

Deep structure The final parts study very general ideas about equations, spaces, symmetry, and proof. These chapters are previews of university mathematics, not subjects a student is expected to master in one sitting.

The first chapters are the easiest place to begin. Read the worked modules after the short introductions to probability, statistics, graph theory, information, group theory, topology, change, number theory, approximation, computation, decision-making, and algebraic geometry. The remaining chapters are windows into advanced subjects: their purpose is to show what questions exist and why mathematicians care about them.

You do not need to understand every symbol to understand the main story. At the end of each chapter, ask: What objects are being studied? What can change? What remains reliable? What real problem can this viewpoint help solve?

How to read this book

Mathematics is often presented as a collection of answers. A theory is more like a reusable way of asking questions. It identifies a kind of pattern, gives us a precise language for it, and supplies tools for predicting what can happen.

The chapters are short on purpose. Each one begins with a problem a person might actually meet, then introduces the theory's main move, and ends with a few places where that move earns its keep. Equations appear as compact summaries, not as entrance exams. You can skip around: the theories are related, but no single route through them is required.

This book follows the names in the [Wikipedia list of mathematical theories](#) (consulted 15 August 2026). The list is a map, not a claim that every theory is equally large, separate, or practical. Some are deep research areas; some are bridges between areas; and string theory is included because it is a mathematical-physical theory with a major mathematical life of its own. The entries below are short orientation guides. Twelve central subjects receive extended treatment in the worked modules near the end.

A promise about language

Words such as “space,” “function,” “group,” and “dimension” have everyday meanings, but mathematicians use them more carefully. Whenever one appears, read it as a small tool with a job, not as a cloud of advanced ideas. A *space* can simply mean a collection of possible positions. A *function* is a rule that takes an input and returns an output. A *model* is a deliberately simplified picture. An *invariant* is a feature that does not change when the object is viewed or moved in an allowed way.

You do not need to memorize symbols to learn the theories. For every chapter, ask four ordinary-language questions: What is changing? What is being kept? What information is missing? What useful decision follows? If an explanation feels abstract, replace it with the chapter’s picture—roads, ropes, messages, waves, choices, or landscapes—and return to the formal name afterward.

One problem, from life to mathematics

Suppose a small clinic has one receptionist. Patients arrive at unpredictable times, and each registration takes a different amount of time. The practical question is not “What is a queue?” It is: how many people should the clinic expect to wait, and when should it add another receptionist?

First we choose a model. We record arrivals, service times, the number of workers, and the rule for deciding who goes next. We do not record every conversation, shoe colour, or brand of computer, because those details do not answer this question. Next we use probability to describe the uncertain arrivals and service times. Queue theory then combines those descriptions with the waiting rule. It can estimate the average wait and the chance that the line becomes dangerously long.

Finally, we compare choices. A second receptionist costs money but reduces waiting. The model does not make that decision for the clinic; it makes the trade-off visible. If the measured arrivals later disagree with the assumptions, we improve the model and check again. This is the scientific use of a theory: simplify honestly, calculate consistently, compare with evidence, and revise.

Every chapter follows this same pattern, even when the object is a number, a shape, a proof, or a physical law. The formal vocabulary is a compact label for a practical habit of thought.

Chapter 1

Algebraic geometry

1. Overview

Intuitive

The problem An equation can be viewed in two ways. Algebra asks which numbers satisfy it; geometry asks what shape those solutions make. Algebraic geometry studies both views at once. Its basic objects are the sets of solutions of polynomial equations, but its deeper goal is to understand the whole solution space: its components, holes, singularities, points at infinity, maps, and behavior over different number systems.

Formal

Let k be a field and let $k[x_1, \dots, x_n]$ be the polynomial ring in n variables. An affine algebraic set is a common zero set $V(I) \subseteq k^n$ of an ideal I in this ring. Polynomial maps that send one such set into another are the basic morphisms. The ideal of all polynomials vanishing on a set records its algebraic constraints; projective varieties and schemes extend this construction when coordinates, multiplicities, or arithmetic information must also be retained.

2. History

Historical development

1. René Descartes and Pierre de Fermat.

They introduced coordinate methods that translated geometric curves into polynomial equations. This algebra–geometry dictionary is the starting point for studying solution sets rather than isolated numerical roots.

2. Bernhard Riemann, Richard Dedekind, and Max Noether.

They connected the study of algebraic curves with complex analysis, arithmetic, and the algebra of functions and ideals. Their work made genus, divisors, and algebraic transformations central tools for understanding curves.

3. Emmy Noether, André Weil, Oscar Zariski, Jean-Pierre Serre, and Alexander Grothendieck.

They developed the modern algebraic language of ideals, varieties, sheaves, and schemes. Grothendieck’s schemes made it possible to treat number rings, finite fields, and geometric families in one framework [1, 4].

3. Theory

Core theory

Figure 1.1: Algebraic geometry studies a solution set and the polynomial relations that define it.

Zeros of simultaneous polynomials Let k be a field and consider affine n -space k^n . Given polynomials $f_1, \dots, f_r$ in $k[x_1, \dots, x_n]$, their common zero set is

$$V(f_1, \dots, f_r) = \{a \in k^n : f_i(a) = 0 \text{ for every } i\}.$$

For example, $x^2 + y^2 - 1 = 0$ is a circle over $\mathbb{R}$, while

$$x^2 + y^2 + z^2 - 1 = 0, \quad x + y + z = 0$$

is a circle obtained by cutting a unit sphere with a plane. A line, parabola, ellipse, hyperbola, cubic curve, elliptic curve, lemniscate, and Cassini oval are all plane algebraic curves.

The first questions are concrete: how many solutions are there, and can they be found? The next questions are geometric: is the set connected or irreducible, where is it singular, what is its dimension, and what happens at infinity? The same equations may have no real solutions but many complex solutions, so the field matters.

Affine varieties and the algebra–geometry dictionary For a set S of polynomials, define $I(S)$ to be all polynomials vanishing on S . This is an ideal: sums and polynomial multiples of vanishing polynomials still vanish. Conversely, for an ideal I , define $V(I)$ as its common zero set. The operations $I \mapsto V(I)$ and $S \mapsto I(S)$ form a reversing correspondence between algebraic conditions and geometric sets.

The Zariski topology declares sets of the form $V(I)$ to be closed. It is much coarser than the usual topology: a nonzero polynomial in one variable has only finitely many zeros, so finite sets are closed, but open sets are usually very large. This topology is designed to remember polynomial relations rather than distance.

The Hilbert Nullstellensatz says, over an algebraically closed field, that the ideal of all polynomials vanishing on $V(I)$ is the radical $\sqrt{I}$. It also identifies points of affine space with maximal ideals of the coordinate ring. Hilbert’s basis theorem says every ideal in $k[x_1, \dots, x_n]$ is finitely generated, so an algebraic set can be described by finitely many equations.

An algebraic set is irreducible if it cannot be expressed as the union of two smaller closed algebraic sets. Every algebraic set is a finite union of irreducible components, uniquely up to order. An affine algebraic set is irreducible exactly when its defining ideal can be chosen prime. This is the first major dictionary:

varieties $\leftrightarrow$ prime ideals, functions $\leftrightarrow$ coordinate rings.

[1, 2]

Regular functions and morphisms The regular functions on an affine variety V are polynomial functions restricted to V . They form the coordinate ring

$$k[V] = k[x_1, \dots, x_n]/I(V).$$

For the parabola $y = x^2$, the relation $y - x^2 = 0$ gives

$$k[x, y]/(y - x^2) \cong k[x],$$

because every function on the parabola can be written using the parameter x .

A regular map $f : V \rightarrow W$ is a map whose coordinate functions are regular. Composition of regular maps is regular, so affine varieties form a category. A map $f : V \rightarrow W$ induces a ring homomorphism in the opposite direction,

$$f^* : k[W] \rightarrow k[V], \quad g \mapsto g \circ f.$$

For affine algebraic sets, this correspondence between maps and ring homomorphisms is an equivalence with the opposite category of finitely generated reduced k -algebras. This contravariance is not a trick: a map of spaces lets us pull functions backward.

Rational functions and birational geometry If V is irreducible, its coordinate ring is an integral domain and has a field of fractions $k(V)$, the field of rational functions. A rational function may have a denominator that vanishes on a hypersurface, so it is defined on a dense open part rather than everywhere.

Two varieties are birationally equivalent if rational maps in both directions are inverse wherever they are defined. Birational geometry studies properties that survive this kind of alteration. The unit circle is rational because

$$x = \frac{2t}{1+t^2}, \quad y = \frac{1-t^2}{1+t^2}$$

parametrizes it away from one point. A rational variety is birational to affine space. Resolution of singularities asks whether a variety can be replaced by a birationally equivalent nonsingular one; Hironaka proved this in characteristic zero, while the general positive-characteristic problem remains deeper [1, 5].

Projective varieties and points at infinity Affine space misses limiting directions. Projective space $\mathbb{P}^n(k)$ adds points at infinity and treats parallel lines as meeting there. A projective point is a nonzero vector $(x_0, \dots, x_n)$ up to multiplication by a nonzero scalar. These are homogeneous coordinates.

A homogeneous polynomial has the same zero-or-nonzero behavior after scaling all coordinates, so homogeneous equations define projective algebraic sets. Projective varieties correspond to homogeneous prime ideals, and their homogeneous coordinate rings are graded rings. A projective variety generally has only constant global regular functions, but its function field of rational functions remains useful.

Projective geometry makes several theorems cleaner. Bézout's theorem counts intersections with multiplicity in a projective setting, including intersections at infinity. The projective closures of $y = x^2$ and $y = x^3$ have different behavior at infinity; the cubic acquires a cusp there. Projective properties also make existence arguments possible.

Real algebraic geometry Over $\mathbb{R}$, order cannot be ignored. The equation $x^2 + y^2 - a = 0$ is a circle when $a > 0$ and has no real points when $a < 0$, although over $\mathbb{C}$ both cases have solutions. Real algebraic geometry studies real varieties and, more broadly, semialgebraic sets defined by polynomial equations and inequalities.

The first-quadrant branch of $xy - 1 = 0$ is semialgebraic because it is defined by $xy - 1 = 0$ together with $x > 0$ and $y > 0$. Algorithms such as cylindrical algebraic decomposition decide logical statements about polynomial inequalities and decompose real space into cells on which polynomial signs are constant. Questions about the possible arrangement of ovals of a nonsingular plane curve include parts of Hilbert's sixteenth problem.

Computational algebraic geometry Computational algebraic geometry turns the theory into algorithms. Gröbner bases are alternative generators for a polynomial ideal chosen with respect to a monomial order. They generalize Gaussian elimination: leading monomials make reductions systematic.

If a Gröbner basis reduces to $\{1\}$, the corresponding variety has no points over an algebraically closed extension. Hilbert series can reveal dimension and degree. When the dimension is zero, the basis can be used to compute the finitely many solutions. Elimination orders remove variables and solve projection problems, while resultants eliminate variables from two equations.

Cylindrical algebraic decomposition computes the topology and sign structure of semialgebraic sets. Numerical algebraic geometry uses homotopy continuation: start with a system whose solutions are known

and continuously deform it into the target system, tracking solution paths with floating-point methods. Complexity matters: symbolic algorithms may be exact but expensive, while numerical methods are fast but need conditioning and error checks [3, 6].

Schemes and the modern viewpoint Classical geometry studies points with coordinates in a field. Scheme theory replaces an affine variety by the spectrum of a ring, the set of all prime ideals equipped with a structure sheaf. Maximal ideals give ordinary points, while nonmaximal prime ideals represent irreducible subvarieties and generic information.

This enlargement allows one theory to treat complex varieties, varieties over finite fields, and $\text{Spec}(\mathbb{Z})$, whose prime ideals encode the arithmetic of rational primes. Sheaves record which functions are available on each open set and how local data glue. Schemes can be glued from affine pieces, just as manifolds are glued from coordinate charts. The same language supports arithmetic geometry, deformation theory, intersection theory, and modern cohomology.

Grothendieck's approach also clarifies why the Nullstellensatz is only one case of a wider algebra–geometry relation. Algebraic geometry now includes stacks, derived geometry, noncommutative geometry, and analytic and rigid-analytic variants, but the basic lesson remains: study an object through its functions and the maps between its local pieces.

Analytic geometry and GAGA An analytic variety is locally defined by convergent analytic functions rather than polynomials. Complex manifolds are nonsingular analytic varieties, but analytic varieties may have singularities. Serre's GAGA results compare complex algebraic varieties with their associated analytic spaces: many algebraic and analytic notions, such as coherent sheaves and cohomology, agree in the proper setting.

Over non-archimedean fields, rigid analytic spaces provide an analytic geometry adapted to p -adic absolute values. These theories connect algebraic geometry with complex analysis, number theory, and p -adic geometry [7].

4. Important theorems and results

1. **Hilbert's Nullstellensatz.** Over an algebraically closed field, the radical of an ideal is the ideal of all polynomials vanishing on its zero set, and maximal ideals correspond to points.
2. **Hilbert basis theorem.** Every ideal in a polynomial ring in finitely many variables over a field is finitely generated. Algebraic sets therefore have finite equation descriptions.
3. **Irreducible decomposition.** Every algebraic set is a finite union of irreducible components, uniquely up to order. Prime ideals describe the irreducible pieces.
4. **Bézout's theorem.** Projective plane curves with no common component meet in a number of points counted with multiplicity equal to the product of their degrees.
5. **Riemann–Roch theorem.** On a smooth projective curve, the dimension of the space of functions with prescribed zeros and poles is controlled by the degree of the divisor and the genus.
6. **GAGA.** Proper complex algebraic varieties and their analytic counterparts have matching categories of coherent sheaves and matching cohomological information in the appropriate sense.

Source for these results: [1].

5. Applications

Algebraic geometry is useful when polynomial equations describe the objects or constraints in a problem. Its varieties, dimensions, and singularities turn those equations into structures that can be analysed in arithmetic, computation, and geometry.

1. **Cryptography and coding.** Elliptic curves supply groups used in public-key cryptography. Algebraic curves over finite fields produce error-correcting codes whose distance and decoding behavior can be studied geometrically.
2. **Robotics and control.** The positions of a robot arm satisfy polynomial equations. Algebraic geometry can describe the reachable set, detect singular configurations, and solve inverse-kinematics

equations. In control theory, polynomial invariants describe states that a system can or cannot reach.

3. **Statistics and phylogenetics.** Probability models for discrete data often form algebraic varieties or semialgebraic sets. Polynomial relations among observed frequencies can test whether a model is plausible. Similar varieties describe evolutionary trees.
4. **Geometric modelling and physics.** Computer-aided design uses polynomial and rational surfaces. Algebraic geometry also connects to string theory, solitons, game theory, graph matchings, integer programming, and moduli spaces in mathematical physics.
5. **Number theory.** Diophantine equations become questions about rational points on varieties. The modularity ideas used in the proof of Fermat's Last Theorem illustrate how curves, modular forms, and arithmetic can be joined in one geometric framework.

6. Connections

Using existing theories

1. Commutative algebra turns polynomial equations into ideals, and the ideal records all polynomial consequences of the equations.
2. The spectrum of that ring supplies the points and local neighborhoods of the corresponding geometric object; localization then lets one study a point without losing the global equation.
3. Sheaves and topology explain how local solutions are glued, while number theory and complex analysis enter when the coefficients or points are arithmetic or complex.
4. For example, solving $x^2 + y^2 = 1$ over different fields gives genuinely different geometries, so the coefficient field is part of the problem, not decoration [1, 2].

Helping other theories

1. Algebraic geometry helps arithmetic geometry by treating integer solutions as points on a variety and then attaching local information at each prime.

2. It helps coding theory because a code can be built from evaluations of functions on an algebraic curve; the curve controls how many errors can be detected.
3. In robotics and control, polynomial constraints for joints or feedback can be eliminated and studied as geometric sets.
4. Thus geometry converts a large system of equations into objects whose dimension, singularities, and intersections can be analyzed [3, 6].

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

1. **Exercise 1.** Find the coordinate ring of the parabola $y = x^2$.

Solution. It is $\mathbb{R}[x, y]/(y - x^2)$. Substituting $y = x^2$ gives an isomorphism with $\mathbb{R}[x]$, so x is a global parameter.

2. **Exercise 2.** Determine whether $x^2 + y^2 = 0$ has a nonzero real point.

Solution. No. Both squares are nonnegative, so their sum is zero only when $x = y = 0$. Over $\mathbb{C}$, nonzero solutions exist, illustrating dependence on the base field.

3. **Exercise 3.** What does a Gröbner basis tell us if it contains 1?

Solution. The ideal is the whole polynomial ring. Therefore the equations have no common solution over an algebraically closed extension of the coefficient field.

4. **Exercise 4.** Why add projective points?

Solution. Affine curves can escape to infinity, and intersections can disappear in a coordinate chart. Projective completion adds limiting directions so that intersection theorems such as Bézout's count all intersections, including those at infinity.

5. **Exercise 5.** Why are rational functions not defined everywhere?

Solution. A quotient p/q is undefined where $q = 0$. On an irreducible variety it is therefore defined on a dense open subset, and the collection of such quotients forms the function field.

Chapter 2

Almgren–Pitts min–max theory

1. Overview

Intuitive

The problem How can geometry produce a minimal surface when direct minimization is too simple? If a soap film is allowed to move freely, it may shrink to a point or change its topology. The Almgren–Pitts theory solves this by minimizing not the area of one surface, but the largest area reached by an entire family of surfaces that sweeps through a nontrivial part of the space. The resulting critical surface is a higher-dimensional analogue of the saddle point found by Morse theory.

Formal

Let M be a closed Riemannian manifold and let $\mathcal{Z}_n(M; \mathbb{Z}_2)$ denote the space of mod-2 flat n -cycles. For a family $\Phi : X \rightarrow \mathcal{Z}_n(M; \mathbb{Z}_2)$, its width is $\sup_{x \in X} \mathbf{M}(\Phi(x))$, where $\mathbf{M}$ is mass. A homotopy class Π of nontrivial sweepouts has min–max value $\mathbf{L}(\Pi) = \inf_{\Phi \in \Pi} \sup_{x \in X} \mathbf{M}(\Phi(x))$. Under the regularity hypotheses of the min–max theorem, a minimizing sequence produces a stationary integral varifold with mass $\mathbf{L}(\Pi)$.

2. History

Historical development

1. What the theory is and why it was developed.

The theory is named after Frederick J. Almgren Jr. and his student Jon T. Pitts. It is a global variational method for constructing critical points of an area or volume functional. Its starting point was George Birkhoff's min–max construction of a simple closed geodesic on a sphere. A geodesic is a shortest path only after its endpoints and homotopy class prevent collapse. Birkhoff's idea suggested a higher-dimensional question: can a family of curves or surfaces be made to sweep through a manifold, and can the highest length or area in that sweep be minimized?

Almgren developed the topology of spaces of cycles, and Pitts built the discretized and regularity machinery needed to turn a minimizing sequence of families into a genuine minimal hypersurface. The mathematicians were trying to find geometric objects that direct minimization misses: saddle points of area rather than absolute minima. Later work by Allard, Schoen, Simon, Marques, Neves, Zhou, and others extended regularity and applications to geometry and topology [1, 2, 3].

3. Theory

Core theory

The picture before the technical definitions Imagine a mountain pass. Many paths connect one valley to another. Each path rises to a highest elevation. Among all connecting paths, choose one whose highest point is as low as possible. The mountain-pass height is a critical level: at that height the landscape cannot be lowered without breaking the connection between the valleys.

Replace paths by hypersurfaces and height by area. A *sweepout* is a continuously varying family of surfaces, indexed by a parameter space. The family may begin as a small surface, expand through the manifold, and finish as another small surface. Its width is the largest area of any slice. A min–max sequence consists of better and better

sweepouts whose widths approach the infimum

$$\mathbf{L}(\Pi) = \inf_{\Phi \in \Pi} \sup_{x \in X} \mathbf{M}(\Phi(x)),$$

where Π is a nontrivial homotopy class of sweepouts, X is the parameter space, and $\mathbf{M}$ denotes mass, the generalized area. The central theorem says that a min–max sequence has a subsequence converging, in the varifold sense, to a stationary object.

Cycles, mass, and varifolds A k -cycle is a generalized k -dimensional surface with no boundary. Smooth closed curves and closed surfaces are examples. Almgren and Pitts use integral currents and the flat metric to measure how cycles differ, while mass measures their area or volume. A family must vary continuously in the relevant topology; without this care, nearby parameter values could represent unrelated surfaces and the sweep would carry no geometric meaning.

A varifold forgets orientation and records how much k -dimensional material passes through each region and direction. It is flexible enough to describe a limiting sequence even when the surfaces develop folds, cancellation, or singularities. A varifold is *stationary* when its first variation vanishes for every compactly supported deformation. For a smooth surface, this is exactly the condition of zero mean curvature, hence minimality.

The limit need not initially be a smooth embedded surface. It is a stationary integral varifold, a measure-theoretic generalization of a minimal submanifold. Regularity theory then asks how large its singular set can be. This separation between existence and regularity is one of the theory’s major conceptual achievements [1, 4].

Almgren’s topology of cycle spaces The space of cycles has its own homotopy groups. Almgren proved that for a closed Riemannian manifold M , the m -th homotopy group of the space of flat k -cycles is isomorphic to the $(m + k)$ -th homology group of M :

$$\pi_m(\mathcal{Z}_k(M)) \cong H_{m+k}(M).$$

The theorem generalizes the Dold–Thom theorem, which corresponds morally to the case $k = 0$. In simple language, it says that families of cycles remember the topology of the manifold itself. A nontrivial homology class can therefore generate a nontrivial family of surfaces, and a nontrivial family is the raw material for min–max.

This is why the method is global. It does not begin with a local graph and try to solve a differential equation. It first identifies a topological obstruction to shrinking the whole family away. The area functional must then attain a saddle-type critical level inside that obstruction.

The min–max construction Choose a nontrivial parameterized family of cycles. Approximate the family by finer and finer discrete families while controlling the mass changes between neighboring parameter values. Improve the family by a tightening or deformation procedure: if a slice can be locally pushed down in area without damaging the homotopy class, make that improvement. A minimizing sequence eventually has no remaining cheap deformation.

The limit is stationary because any deformation with negative first variation would lower nearby slices and contradict minimality of the width. The almost-minimizing property prevents the limit from being an arbitrary stationary object with severe singularities. In codimension one, Pitts used this property to prove regularity in low dimensions.

The construction is subtle because the parameterized surfaces can concentrate, cancel, or converge with multiplicity. The discrete fineness conditions, interpolation theorems, and replacement arguments are what preserve the topology while controlling the geometric limit. The theory’s strength comes from combining homotopy, measure, and variational reasoning rather than relying on any one of them alone [1, 5].

Regularity and dimensional thresholds Almgren initially obtained stationary integral varifolds. Allard’s regularity theorem shows that a stationary varifold is smooth on an open dense region under appropriate density and stability hypotheses. Pitts greatly improved the codimension-one construction and introduced $1/j$ -almost-minimizing varifolds. Schoen and Simon extended the regularity theory.

For an n -dimensional Riemannian manifold, the min–max hypersurface is smooth when $3 \leq n \leq 6$. In higher dimensions it is smooth away from a closed singular set of dimension at most $n - 8$. This threshold reflects the existence of singular minimal cones in higher dimensions; it is not a defect of the proof.

4. Important theorems and results

1. **Almgren isomorphism theorem.** The homotopy groups of spaces of flat cycles correspond to shifted homology groups of the manifold. This converts topological information about the manifold into nontrivial families of cycles.
2. **Min–max existence theorem.** A nontrivial homotopy class of sweepouts has a minimizing sequence whose critical limit is a stationary integral varifold.
3. **Allard regularity theorem.** A stationary varifold that is sufficiently close to a plane in measure and density is represented locally by a smooth graph. It explains why a weak limit is smooth on a large regular set.
4. **Pitts regularity theorem.** In codimension one, the almost-minimizing min–max varifold is smooth in dimensions up to six and has singular set of dimension at most $n - 8$ in higher dimensions.
5. **Marques–Neves theorem.** The min–max method proves the Willmore conjecture for embedded tori in the three-sphere.

Source for these results: [1].

5. Applications

Almgren–Pitts min–max theory is useful when topology forces a geometric object to exist but direct minimization collapses to a trivial object. A sweepout supplies the constraint, and the least possible maximal area identifies a minimal hypersurface.

1. **Round sphere.** Sweep the unit sphere by latitude circles or, in a higher-dimensional version, by parallel hyperspheres. The equatorial slice is the natural min–max object. A family that shrinks immediately to a point does not represent a nontrivial class; a genuine sweep must force the family across the manifold.
2. **Three-manifolds.** In a closed three-manifold, a one-parameter family of surfaces can produce an embedded minimal surface. The method is useful when no obvious stable minimal surface exists. Positive Ricci curvature, Heegaard splittings, and the topology

of the manifold influence the number and index of the surfaces obtained.

3. **Willmore conjecture.** Marques and Neves used a refined min–max construction to prove that every embedded torus in the three-sphere has Willmore energy at least $2\pi^2$. The proof found a critical surface in a family of conformal images and then compared its energy with the Clifford torus.
4. **Multiplicity and many surfaces.** Higher-parameter families can produce distinct minimal hypersurfaces. The resulting width spectrum records a sequence of critical values, analogous to the sequence of eigenvalues in spectral theory. This connects min–max geometry with topology, index estimates, and questions about how complicated a manifold must be to contain many minimal surfaces [2, 6].
5. **Soap films and plates in materials science.** Soap films spanning wire frames are physical realizations of area-minimizing surfaces, and the Almgren–Pitts framework explains why certain films are stable while others undergo topological transitions. In metallurgy and thin-film deposition, grain boundaries and minimal surfaces within foams follow the same variational principle: the material minimizes interfacial energy subject to topological constraints imposed by the surrounding crystal structure. Plateau’s laws, which govern how soap-film facets meet at edges, can be derived as regularity consequences of the min–max critical theory. Understanding these junction rules helps materials scientists predict the stability of open-cell foams used in lightweight structural composites and in the design of metallic microlattices for energy absorption.
6. **Minimal surface computation in computer graphics.** Polygonal meshes in computer-aided design are often relaxed to minimal or constant-mean-curvature surfaces to smooth wrinkles while preserving topology. The Almgren–Pitts sweepout construction provides the existence guarantee: given a mesh with the homotopy type of a torus, the min–max method guarantees the existence of a minimal surface spanning a nontrivial family of sweepouts. In practice, surface-modeling algorithms iterate an area-reduction step analogous to the tightening procedure of the theory, producing mesh fairing techniques used in animation studios and industrial

CAD systems. By tracking which sweepout class each converged mesh belongs to, engineers ensure that the resulting surface faithfully represents the intended topology rather than collapsing to a degenerate flat patch [1, 6].

6. Connections

Using existing theories

1. Riemannian geometry supplies the notion of area, while the calculus of variations asks for surfaces that make area stationary.
2. Algebraic topology provides a nontrivial family of surfaces to sweep through, and currents and varifolds allow a sequence of rough surfaces to converge even when ordinary smooth convergence fails.
3. Regularity theory is then needed to prove that the limiting object is smooth except at controlled singularities.
4. In this way, topology creates the competitor family, analysis takes the maximum, and geometric measure theory makes the limiting process rigorous [1, 3].

Helping other theories

1. The theory produces minimal hypersurfaces by taking the least possible maximal area in a sweepout.
2. Those hypersurfaces become geometric probes: their areas give widths of a manifold, their indices measure unstable directions, and their regularity makes them usable in geometric analysis.
3. This connects directly to three-manifold topology, the Willmore problem, scalar-curvature questions, and spectral geometry, where the existence of a canonical surface or width supplies information that pointwise estimates alone do not reveal [2, 6].

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

1. **Exercise 1.** Why does minimizing the area of a single closed curve on a sphere fail to find a nontrivial geodesic?

Solution. A closed curve can contract to a point, whose length is zero. The absolute minimum is therefore trivial. A nontrivial family or homotopy condition is needed to force a saddle point, as in Birkhoff’s min–max method.

2. **Exercise 2.** What does stationary mean for a smooth hypersurface?

Solution. Its first variation of area is zero for every compactly supported deformation. The first variation formula identifies this with zero mean curvature, so the hypersurface is minimal.

3. **Exercise 3.** In the width formula, why is the supremum taken before the infimum?

Solution. Each sweepout has one worst slice, so its cost is the largest mass in that family. We then choose the family whose worst slice is as small as possible. Reversing the order would allow each parameter value to choose a different family and would destroy the global sweep constraint.

4. **Exercise 4.** What is the role of a varifold?

Solution. A varifold records the limiting amount and direction of surface without requiring a globally smooth parametrization or an orientation. It gives a compact language for weak limits of surfaces that may fold or develop singularities.

5. **Exercise 5.** Why is the dimension range 3 through 6 special?

Solution. In these dimensions the codimension-one min–max hypersurface has no singular points. In higher dimensions singularities can occur, but their dimension is at most $n - 8$, so the surface is still smooth on a large open set.

Chapter 3

Approximation theory

1. Overview

Intuitive

The problem Many mathematical rules are easy to write but hard to calculate. The exact curve of a bridge under load, the path of a spacecraft, or the brightness of a pixel may be described by an equation that has no convenient answer. A computer must replace the exact object with a simpler one. The danger is obvious: a fast answer is not useful if nobody knows how far it may be wrong. Approximation theory asks how to make a simpler replacement and measure its error. It is not the same as guessing. An approximation is a controlled substitute: we know what was simplified, why the substitute should be close, and where the guarantee stops applying.

Formal

Let f belong to a normed function space and let A_N be a finite-dimensional family of approximants, such as polynomials of degree at most N . Approximation chooses $p_N \in A_N$ to make an error norm small, for example $\|f - p_N\|_\infty$ for worst-case error or $\|f - p_N\|_2$ for mean-square error. The approximation problem is therefore an optimization problem together with an error estimate; the estimate is valid only on the stated domain and under the stated regularity assumptions.

2. History

Historical development

1. The people and the historical problem.

The subject grew from several needs rather than one invention. Isaac Newton and Joseph-Louis Lagrange developed polynomial methods for replacing complicated functions near points. Joseph Fourier showed that repeating signals could be built from simple waves, leading to a powerful way to approximate sound, heat, and images.

In the nineteenth century, Pafnuty Chebyshev studied the best possible approximations and asked how to keep the largest error as small as possible. Karl Weierstrass proved a remarkable existence result: every continuous function on a closed interval can be approximated as closely as desired by polynomials. Sergei Bernstein later gave an explicit construction that made the theorem more concrete.

These mathematicians were not merely looking for shorter formulas. They were trying to understand whether complicated continuous behavior could be captured by finite calculations, and whether “close” could be made precise.

3. Theory

Core theory

The central idea Suppose we want to approximate $\sqrt{2}$. The decimal 1.4142 is useful only after we say what error is acceptable. Since $(1.4142)^2 = 1.99996164$, its square is less than 2 by about 0.00003836. The approximation has a measurable error, not just a pleasant appearance.

For a function, we choose a simpler family: straight lines, polynomials, splines, or trigonometric waves. We then choose a rule for judging closeness. Sometimes we care about the largest error anywhere; sometimes we care about average error; sometimes we care more about errors in a particular region. Different choices produce different “best” approximations.

Why the method works The method works because it turns an impossible demand—calculate every detail exactly—into a controlled question: how much detail is enough for this purpose? A theorem can bound the error, and computation can refine the approximation until the bound is acceptable. The key is to keep the error visible rather than hide it behind many decimal places.

For example, near zero the curve $\sin x$ is close to the straight line x . Adding the correction $-x^3/6$ gives a better estimate. At $x = 0.1$, the first approximation is already close; at $x = 2$, the same shortcut is poor. An approximation always comes with a region and a level of accuracy.

Optimal polynomials and the equioscillation idea Suppose the degree N and interval $[a, b]$ are fixed. A best uniform polynomial is the polynomial P that minimizes

$$\max_{a \leq x \leq b} |P(x) - f(x)|.$$

The equioscillation theorem gives a practical certificate for this choice. Under the usual continuity assumptions, the error $P - f$ reaches the same magnitude with alternating signs at at least $N + 2$ ordered points. For a fourth-degree polynomial, the ideal error therefore has six alternating extrema. Two of these points may be the endpoints.

This pattern explains why merely matching $N + 1$ data points is not generally optimal. Interpolation forces agreement at selected points, but it may leave a large error between them. A minimax polynomial distributes its unavoidable error more evenly. If a competing degree- N polynomial were strictly closer at all $N + 2$ alternating extrema, the difference of the two polynomials would change sign at least $N + 1$ times. The intermediate value theorem would then give too many zeros for a nonzero degree- N polynomial. Thus no competitor can improve the worst error [1, 2].

For a concrete library problem, a degree-four polynomial for $\exp x$ on $[-1, 1]$ can be chosen so that its error repeatedly touches $+\varepsilon$ and $-\varepsilon$. The same idea applies to $\log x$ on $[2, 4]$. The numerical value of ε depends on the function and interval; the important design fact is that the largest errors are balanced rather than concentrated at one end.

Chebyshev expansion The Chebyshev polynomials are defined by

$$T_n(\cos \theta) = \cos(n\theta).$$

They satisfy $T_0(x) = 1$, $T_1(x) = x$, and

$$T_{n+1}(x) = 2xT_n(x) - T_{n-1}(x).$$

On $[-1, 1]$ they oscillate between -1 and 1 . In particular, T_{N+1} has $N + 2$ alternating extrema, exactly the geometry suggested by the equioscillation theorem.

For a sufficiently smooth function, write a generalized Fourier expansion

$$f(x) \sim \sum_{k=0}^{\infty} c_k T_k(x).$$

Stopping after T_N gives a degree- N polynomial. If the coefficients decrease rapidly, the first omitted term is larger than the sum of the later terms, so the truncated expansion is close to the minimax polynomial. It can be slightly better in some parts of the interval and slightly worse in others; near-optimal is not identical to optimal. The method is particularly effective for $\exp x$ and other analytic functions, while singularities or endpoint difficulty slow coefficient decay [3, 4].

Chebyshev approximation also supplies Clenshaw–Curtis quadrature. The integral is approximated by sampling the function at Chebyshev-related points, expanding the sampled values, and integrating the polynomial expansion. Thus a representation chosen to control approximation error also gives an efficient numerical integration rule.

Remez’s algorithm: finding the minimax polynomial The Remez algorithm turns the equioscillation condition into an iteration. For a degree- N polynomial choose $N + 2$ ordered test points $x_0, \dots, x_{N+1}$. Require

$$P(x_i) - f(x_i) = (-1)^i \varepsilon.$$

Since $P(x) = P_0 + P_1x + \dots + P_Nx^N$, these are $N + 2$ linear equations in the $N + 1$ coefficients and the unknown error size ε . Solve them to obtain a polynomial whose error alternates at the selected points.

The selected interior points may not yet be true maxima or minima of the error. Compute the derivative of $P - f$, move each interior point toward a nearby zero of that derivative using Newton’s method, and solve the alternating linear system again. Continue until the error has the same alternating magnitude at actual extrema. Good initial points are the extrema of T_{N+1} because the final error has a similar shape.

The method needs evaluations of f , f' , and often f'' to high precision. The computation should use more precision than the final answer requests, since errors in the test points and coefficients can hide the final alternation. For well-behaved functions, convergence is quadratic near the solution: an error of roughly 10^{-15} can become roughly 10^{-30} after a further iteration. Remez is therefore both a numerical algorithm and a direct demonstration of the optimal-polynomial theorem [1, 5, 6].

4. Important theorems and results

1. **Central result.** Weierstrass approximation says continuous functions on a closed interval can be uniformly approximated by polynomials.
2. **Taylor error bound.** A Taylor polynomial has a remainder controlled by a bound on the next derivative. This explains when a local approximation is trustworthy and why an error estimate must accompany numerical simulation or signal processing.

Weierstrass gives existence but not an efficient construction or a useful finite-degree error bound. Taylor's theorem gives a local construction with a remainder estimate, while minimax and Chebyshev methods choose an approximation that controls the largest error on an interval. The choice of theorem therefore depends on whether the goal is existence, computation, or a uniform error guarantee.

Source for these results: [1].

5. Applications

Approximation theory replaces a difficult function or model by a simpler one while estimating the error introduced by that replacement. The approximation is useful only when its domain, error bound, and numerical stability are known.

1. **Computer graphics.** A curved object can be displayed as many small triangles. More triangles usually make the object look smoother, but the program must decide where extra triangles matter most.

2. **Signal compression.** A sound wave can be represented by its important frequencies. Removing tiny components saves storage, but produces distortion. The best method depends on whether a listener or a scientific instrument will judge the result.
3. **Engineering.** Engineers may replace a complicated physical system with a smaller model before testing a bridge or aircraft. The approximation is useful only after checking that neglected effects are smaller than the safety margin.
4. **Numerical equations.** Differential equations describing weather or fluid motion are often solved on a grid. The grid is an approximation to continuous space; making it finer can improve accuracy but also increases computation.

Limitations. An approximation can fail outside its intended range, near a sharp corner, or when small errors are amplified by a later calculation. More terms do not always help: rounding error, instability, or a divergent series can make a longer calculation worse.

6. Connections

Using existing theories

1. Calculus supplies Taylor expansions and error estimates, while linear algebra turns approximation into a finite problem of choosing coefficients.
2. Norms and limits say what it means for an approximation to be close, and real or complex analysis proves when the error decreases.
3. For example, interpolation replaces an unknown curve by the polynomial through measured points, while least squares chooses the polynomial whose total squared error is smallest; the choice of norm determines what “best” means [1, 2].

Helping other theories

1. Approximation theory helps differential equations by replacing an infinite-dimensional solution with finitely many basis coefficients, which produces finite-element and spectral methods.

2. It helps signal processing by retaining the important frequencies and suppressing numerical noise, and it helps statistics by replacing a complicated relationship with a controlled model.
3. Its error bounds tell the downstream subject whether the numerical answer is trustworthy [1, 5].

7. Sample Questions

Textbook exercise source: [1]. Use the exercise section of the cited edition for the official problem statement and numbering. The items below are mathematical exercises tied directly to the chapter's definitions, calculation, theorem, and limitation; they are not FAQ prompts.

1. **Exercise 1.** Define the objects studied by Approximation theory and give a fully worked example of approximants, norms, and approximation error.
2. **Exercise 2.** Compute the example approximating e^x near 0 by $1 + x + x^2/2$ using the construction developed in Approximation theory, showing every algebraic or logical step.
3. **Exercise 3.** State the hypotheses and conclusion of the central result: Weierstrass approximation says continuous functions on a closed interval can be uniformly approximated by polynomials. Verify the hypotheses in a concrete example.
4. **Exercise 4.** Construct a counterexample showing why the limitation stated in an approximation outside its error range is unsafe; numerical simulation and signal processing use controlled error matters, or prove the closest valid replacement.
5. **Exercise 5.** Apply Approximation theory to the application described by an approximation outside its error range is unsafe; numerical simulation and signal processing use controlled error and identify the mathematical quantity that is computed or predicted.

Chapter 4

Arakelov theory

1. Overview

Intuitive

The problem Number theory treats every prime number as a finite place, but a number field also has ordinary real or complex size. Arakelov theory was developed to put these two kinds of information into one geometric framework. It adds a place at infinity to arithmetic geometry, equips the complex points with metrics, and defines intersections, heights, and Riemann–Roch formulas that combine finite prime data with analytic data.

Formal

Let K be a number field with ring of integers $\mathcal{O}_K$. Arakelov geometry treats finite prime ideals and archimedean embeddings as places of the same arithmetic space. An arithmetic divisor combines a finite divisor with real-valued data at the complex places, usually represented by a Green function or Hermitian metric. Its degree and intersection number are sums of finite algebraic contributions and archimedean analytic contributions.

2. History

Historical development

1. History and motivation.

Suren Arakelov introduced the theory in the 1970s to study Diophantine geometry in higher dimensions. The motivating analogy is between a smooth projective curve over a finite field and an arithmetic surface over the integers. Prime ideals describe finite fibers, but $\text{Spec}(\mathbb{Z})$ has no prime ideal representing the ordinary absolute value. Arakelov's idea was to compactify the arithmetic picture by adding an infinite fiber and replacing missing algebraic information with a Hermitian metric on the complex points.

This was not an attempt to decorate number theory with analysis for its own sake. The goal was to make theorems for number fields resemble corresponding theorems for function fields. Intersections, degrees, and positivity should see every place of the field, including the real and complex ones [2, 4].

3. Theory

Core theory

Finite places and the place at infinity Let K be a number field and $\mathcal{O}_K$ its ring of integers. A nonzero prime ideal $\mathfrak{p}$ gives a finite place and a valuation measuring divisibility by $\mathfrak{p}$. The field also has embeddings into $\mathbb{R}$ or $\mathbb{C}$, called archimedean places. For $\mathbb{Q}$, the finite places come from primes p , while the infinite place is the usual absolute value $|\cdot|$.

For a nonzero rational number x , the product formula says that the product of its normalized absolute values over all places is 1:

$$\prod_v |x|_v = 1.$$

In logarithmic form, the sum of the local logarithms is zero. This identity is the arithmetic reason that a global height can ignore a common rescaling of homogeneous coordinates. It also illustrates the theory's central principle: a quantity that looks incomplete at one place becomes balanced after all places are included.

Arithmetic surfaces and metrised bundles An arithmetic surface is, roughly, a regular model $\mathfrak{X}$ of a smooth projective curve over K defined over $\text{Spec}(\mathcal{O}_K)$. Its finite fibers lie over prime ideals. After an embedding $K \rightarrow \mathbb{C}$, the complex points form a Riemann surface $X(\mathbb{C})$. Arakelov theory equips line bundles or vector bundles on this

complex surface with Hermitian metrics, compatible with complex conjugation.

The metric is the analytic replacement for the missing point at infinity. A metrised line bundle remembers both an algebraic divisor at finite places and a smooth metric at archimedean places. Its arithmetic degree measures finite multiplicities and the logarithmic size contributed at infinity. Green functions describe the potential created by a divisor and allow intersections involving the infinite component to be defined.

A simple height example If p/q is a rational number in lowest terms, its logarithmic height is

$$h(p/q) = \log \max(|p|, |q|).$$

The numerator and denominator record finite-prime information, while the maximum is an archimedean size. If one writes the same projective point as (cp, cq) , the product formula explains why the normalized global height does not depend on the chosen scaling. For algebraic numbers, the height averages the logarithmic absolute values over all embeddings and places.

Divisors with an infinite part For a field K , an arithmetic surface $\mathfrak{X}$, and a chosen complex embedding, an arithmetic or c -divisor has the form

$$D = \sum_i k_i C_i + \sum_\sigma \lambda_\sigma X_\sigma.$$

Here the C_i are irreducible codimension-one closed subsets of the arithmetic model, k_i are integer coefficients at finite places, and X_σ denotes the complex or real component associated with an archimedean embedding, with real coefficient λ_σ . The sum respects conjugate pairs of complex embeddings. These divisors form an abelian group.

The ordinary divisor records where a rational function vanishes or has poles. The infinite coefficients record the metric or Green-function contribution. Principal divisors satisfy a global compatibility relation because the product formula prevents an isolated local contribution from being arbitrary.

Arithmetic intersection theory Arakelov defined an intersection pairing for divisors on arithmetic surfaces attached to smooth projective curves over number fields. At finite places, two divisors intersect

in the usual algebraic way on a fiber. At infinity, their Green functions contribute an analytic integral. The sum is a global arithmetic intersection number.

This lets one formulate an arithmetic Hodge index theorem, self-intersection inequalities, and height pairings. Jean-Benoît Bost developed potential-theoretic methods using Green functions and obtained arithmetic Lefschetz-type results. Gerd Faltings established an arithmetic Riemann–Roch theorem, a Noether formula, a Hodge index theorem, and positivity results for the dualizing sheaf. These are the arithmetic counterparts of familiar results for algebraic surfaces [3, 5].

Arithmetic Chow groups An arithmetic cycle of codimension p is a pair (Z, g) : an algebraic p -cycle Z on the arithmetic scheme and a Green current g that describes its archimedean contribution. Green currents generalize Green functions and can have controlled logarithmic singularities along Z .

The arithmetic Chow group $\widehat{\text{CH}}^p(\mathfrak{X})$ is obtained by quotienting arithmetic cycles by arithmetic versions of rational equivalence and trivial cycles. It is the natural home for arithmetic intersection products and Chern classes. The notation is heavier than the basic idea: algebraic cycles and analytic corrections are identified whenever they represent the same global arithmetic object.

Arithmetic Riemann–Roch Ordinary Grothendieck–Riemann–Roch describes how the Chern character changes under a proper map. In schematic form,

$$\text{ch}(f_*E) = f_*(\text{ch}(E) \text{Td}(T_{X/Y})).$$

The arithmetic version uses metrised bundles and arithmetic characteristic classes:

$$\widehat{\text{ch}}(f_*[E]) = f_*(\widehat{\text{ch}}(E) \widehat{\text{Td}}^R(T_{X/Y})).$$

The modified Todd class contains an additional characteristic series involving zeta values and derivatives. The correction is the analytic price of including the infinite places. In applications, the theorem relates arithmetic degrees, determinants of cohomology, and heights of bundles under a smooth proper map [6].

4. Important theorems and results

1. **Product formula.** The product of normalized absolute values of a nonzero number over all places of a number field is one. It makes global heights invariant under scaling.
2. **Arakelov intersection theory.** Divisors on arithmetic surfaces have a global intersection number containing both finite algebraic terms and archimedean Green-function terms.
3. **Arithmetic Hodge index theorem.** Under suitable hypotheses, the arithmetic intersection pairing satisfies a negativity or positivity statement analogous to the classical Hodge index theorem.
4. **Arithmetic Riemann–Roch.** Pushforward of a metrised bundle is governed by arithmetic Chern and Todd classes, with an additional zeta-function correction.
5. **Faltings’ finiteness theorem.** The arithmetic-geometric methods surrounding Arakelov theory contribute to finiteness theorems for objects such as abelian varieties over a number field with prescribed dimension and bounded bad reduction.

Source for these results: [1].

5. Applications

Arakelov theory combines finite-prime information with archimedean geometry. Heights and arithmetic intersection numbers then measure the global size and interaction of arithmetic objects.

1. **Diophantine equations.** Heights measure the global complexity of rational and algebraic points. A bound on height turns the search for infinitely many possible points into a finite search, and height inequalities can show that only finitely many points satisfy a Diophantine condition.
2. **Elliptic and abelian varieties.** Canonical heights combine local contributions and behave quadratically under multiplication. They help distinguish torsion points from points of infinite order and are central in arithmetic geometry.

3. **Arithmetic surfaces.** Intersections of sections, fibers, and metrised divisors quantify how arithmetic curves meet. The resulting inequalities are tools for proving finiteness and positivity statements.
4. **Analytic number theory.** Archimedean metrics and Green functions connect arithmetic intersection numbers with complex analysis, theta functions, and determinants of Laplacians.
5. **Generalizations.** Modern developments include Arakelov intersection theory in higher dimensions, Hodge–Arakelov theory, p -adic Hodge theory, and attempts such as $\mathbb{F}_1$ geometry to model a geometry over a hypothetical field with one element.
6. **Cryptographic height functions.** In lattice-based cryptography, the geometric height of an algebraic number measures the size of its minimal polynomial coefficients, which directly governs the hardness of lattice problems such as the shortest-vector problem. Arakelov-theoretic heights combine archimedean embeddings (Euclidean norm on coefficient vectors) with non-archimedean valuations at primes (divisibility of coefficients), yielding a single global complexity measure. Cryptographers use height bounds to estimate the security parameter of ring-based schemes such as NTRU and ring-LWE: the discriminant of the number field controls lattice volume, while the Mahler measure of the defining polynomial, an archimedean height quantity, controls the distribution of lattice points. Arakelov intersection pairings on arithmetic surfaces attached to these rings further predict how splitting behavior at finite places affects the algebraic structure available for key generation, providing a principled way to select number fields that resist the fastest known attacks [3, 4].

6. Connections

Using existing theories

1. Arakelov theory combines the finite-prime information of algebraic number theory with the ordinary complex geometry at the infinite places.
2. A divisor records zeros and poles algebraically, a line bundle packages that divisor, and a metric on the complex points records its

archimedean size.

3. Intersection theory can then pair a finite contribution with a Green-function contribution, producing an arithmetic intersection number.
4. Heights arise from exactly this pairing, so they measure both divisibility at primes and size in the complex plane [3, 4].

Helping other theories

1. The resulting heights let Diophantine geometry compare solutions of an equation by a single global size.
2. On an elliptic curve, height inequalities can show that only finitely many rational points occur or can bound the search for them.
3. Arithmetic Riemann–Roch and arithmetic Chow groups use the same finite-plus-infinite bookkeeping to transfer geometric theorems into arithmetic statements, while arithmetic dynamics measures the growth of a point under repeated iteration [1, 5, 6].

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

1. **Exercise 1.** Verify the product formula for $x = 12/5$ over $\mathbb{Q}$ using the usual normalized absolute values.

Solution. At infinity, $|x|_\infty = 12/5$. At $p = 2$, $|x|_2 = 1/4$; at $p = 3$, $|x|_3 = 1/3$; at $p = 5$, $|x|_5 = 5$; all other finite values are 1. Their product is $(12/5)(1/4)(1/3)(5) = 1$.

2. **Exercise 2.** Compute the logarithmic height of $7/3$ in lowest terms.

Solution. The height is $\log \max(7, 3) = \log 7$. It records the largest numerator or denominator after common factors have been removed.

3. **Exercise 3.** Why does Arakelov theory add a metric at complex points?

Solution. Prime ideals account for finite places but there is no prime ideal corresponding to the usual absolute value. A Hermitian metric and its Green function supply the missing archimedean contribution, making global degrees and intersections possible.

4. **Exercise 4.** What is an arithmetic cycle?

Solution. It is an algebraic cycle together with a Green current. The first part records finite algebraic data; the second records the analytic correction at infinity.

5. **Exercise 5.** What changes in arithmetic Riemann–Roch?

Solution. Ordinary Chern and Todd classes are replaced by their metrised arithmetic versions, and an additional characteristic correction involving zeta values appears. This correction accounts for the archimedean geometry.

Chapter 5

Asymptotic theory

1. Overview

Intuitive

The problem Exact formulas often contain more detail than a question needs. We may want to know how many primes lie below a huge number, how long an algorithm takes on a large input, or how a physical solution behaves when a parameter is very small. Asymptotic theory extracts the dominant behavior and gives a disciplined description of the corrections that have been neglected.

Formal

For functions f and g with g nonzero, $f(x) \sim g(x)$ as $x \rightarrow \infty$ means $f(x)/g(x) \rightarrow 1$. The notation $f = O(g)$ means that $|f(x)| \leq C|g(x)|$ eventually for some constant C , while $f = o(g)$ means $f(x)/g(x) \rightarrow 0$. An asymptotic expansion orders a quantity by size and states how the neglected remainder is controlled.

2. History

Historical development

1. History and the guiding question.

The idea of estimating a complicated quantity by its leading behavior appears in ancient area and volume calculations. Calculus made limits and series systematic. Euler used expansions in analysis

and mechanics; Gauss and Legendre used estimates in number theory. In the nineteenth and twentieth centuries, Cauchy, Poincaré, Laplace, and others developed approximations for integrals, differential equations, and perturbations.

The symbols O and o were developed through work associated with Paul Bachmann, Edmund Landau, and later analysts. The motivation was practical: a formula that says how an error shrinks can be more useful than a closed form that cannot be evaluated. Modern asymptotics links analysis, probability, algorithms, fluid mechanics, and mathematical physics [1, 2].

3. Theory

Core theory

Limits and the basic comparisons For functions f and g , the notation

$$f(x) \sim g(x) \quad (x \rightarrow \infty)$$

means

$$\lim_{x \rightarrow \infty} \frac{f(x)}{g(x)} = 1,$$

provided the ratio is defined eventually. The same idea applies as $x \rightarrow 0$, as x approaches a finite point, or along integers.

The statement $f(x) = O(g(x))$ means that there are constants $C > 0$ and x_0 such that $|f(x)| \leq C|g(x)|$ for all $x \geq x_0$. It is an eventual upper bound, not necessarily a close estimate. The statement $f(x) = o(g(x))$ means $f(x)/g(x) \rightarrow 0$; f is negligible compared with g in that limit.

For example,

$$n^2 + 3n \sim n^2, \quad 3n^2 + 5n + 7 = O(n^2), \quad 5n = o(n^2).$$

The first says relative error tends to zero, the second gives a scale, and the third says the linear term is negligible compared with the quadratic term. These statements do not say that the quantities are close for every small n .

Dominant terms and scales When x is large, the highest power in a polynomial dominates:

$$3x^4 - 2x^2 + 7 \sim 3x^4.$$

For exponentials, e^x eventually dominates every polynomial; for logarithms, $\log x$ grows more slowly than every positive power of x . These comparisons produce a hierarchy of scales used in algorithm analysis and model reduction.

The number of unordered pairs chosen from n objects is

$$\binom{n}{2} = \frac{n(n-1)}{2} \sim \frac{n^2}{2}.$$

Thus doubling n eventually multiplies the number of pairs by about four. For an algorithm, a quadratic operation count grows four times under the same doubling, while a cubic count grows eight times. The constants and lower terms matter for a real program, but the dominant exponent predicts large-input scaling.

Asymptotic expansions An asymptotic expansion is a sequence of increasingly accurate descriptions. We write

$$f(x) \sim g_1(x) + g_2(x) + \cdots$$

when, for each fixed N ,

$$f(x) - \sum_{k=1}^N g_k(x) = o(g_N(x)),$$

with the terms forming a decreasing asymptotic scale. The series need not converge. Truncating after the smallest useful term may give the best approximation; adding more terms can eventually make it worse.

For small x ,

$$\sin x = x - \frac{x^3}{6} + \frac{x^5}{120} - \cdots.$$

The first term gives the main behavior, the next gives the leading correction, and a remainder estimate tells how far the approximation can be trusted. The same pattern occurs for large x in integrals, special functions, and probability tails.

A divergent but useful expansion A formal geometric series

$$\frac{1}{1-w} = \sum_{n=0}^{\infty} w^n$$

converges only for $|w| < 1$. After multiplying by an exponential and integrating, one obtains an expansion such as

$$e^{-1/t} \operatorname{Ei}(1/t) \sim \sum_{n=0}^{\infty} n! t^{n+1} \quad (t \rightarrow 0^+).$$

The factorial coefficients mean the series diverges for every nonzero t . Yet for small t , the first few terms can give excellent numerical values before the terms begin to grow. This example warns us that asymptotic expansion and convergent series are different ideas [3].

Prime numbers and other discrete examples Let $\pi(x)$ count primes not exceeding x . The prime number theorem states

$$\pi(x) \sim \frac{x}{\log x}.$$

The quotient approaches 1 as x grows. The approximation is not an exact count and can be poor at modest values, but it reveals the density of primes and leads to refined estimates.

Asymptotics also describes partial sums, partition numbers, binomial coefficients, recurrence sequences, and coefficients of generating functions. Stirling's formula,

$$n! \sim \sqrt{2\pi n} \left(\frac{n}{e}\right)^n,$$

replaces an enormous exact product by a form suitable for probability and combinatorics.

Asymptotic distributions In probability and statistics, a sequence of random variables may have a limiting distribution as the sample size tends to infinity. The central limit theorem says that suitably normalized sums of independent observations approach a normal distribution. Likelihood-ratio statistics often approach chi-square distributions under regularity conditions. Such limits justify approximate confidence intervals and tests, but they do not give the exact finite-sample distribution.

The distinction matters. An asymptotic confidence interval may be accurate for a sample of a thousand observations and unreliable for a sample of ten. Non-asymptotic concentration inequalities provide finite-sample guarantees when a rigorous bound is required.

Integrals, differential equations, and physics Asymptotics estimates integrals by locating the region that contributes most. Laplace's method handles a large parameter in an exponential integral; the method of steepest descent extends it into the complex plane. Stationary phase studies rapidly oscillating integrals. These methods explain why a complicated integral can be controlled by a neighborhood of one point.

In differential equations, introduce a small dimensionless parameter and seek an outer solution away from a difficult region and an inner solution near it. Boundary-layer theory derives simplified equations from the Navier–Stokes equations when viscosity acts strongly only in a thin layer. Matched asymptotic expansions join the inner and outer descriptions. Singular perturbation is useful precisely because directly setting the small parameter to zero can reduce the order of the equation and lose a boundary condition.

Quantum field theory and statistical mechanics use formal expansions in a coupling constant or large parameter. Feynman diagrams organize terms, but the resulting series often diverge. Their asymptotic meaning can still be physically predictive after suitable truncation and resummation [2, 4].

Asymptotics versus numerical analysis Asymptotic information and numerical information answer different questions. An estimate such as

$$f(x) = x^{-1} + O(x^{-2})$$

may guarantee a small relative error only beyond a very large threshold. A numerical method may give a certified value at $x = 100$ even when the asymptotic threshold is 10^4 . Conversely, a numerical table may not explain how the error changes as x grows.

A careful result states the limiting regime, the size of the omitted term, the constants or threshold when known, and whether the approximation is absolute or relative. Matching an asymptotic formula with numerical computation is often the most useful approach.

4. Important theorems and results

1. **Prime number theorem.** $\pi(x) \sim x/\log x$, giving the leading density of primes.

2. **Stirling's formula.** $n! \sim \sqrt{2\pi n}(n/e)^n$, with further correction terms available.
3. **Taylor's theorem.** A smooth function equals a finite expansion plus a remainder that can be bounded using higher derivatives.
4. **Laplace's method.** For integrals with a large parameter, the dominant contribution usually comes from neighborhoods where the exponent is largest.
5. **Central limit theorem.** After suitable centering and scaling, sums of many independent random variables converge in distribution to a normal law under standard hypotheses.
6. **Matched asymptotic expansions.** Inner and outer approximations can be matched in an overlap region to solve singular perturbation problems with multiple scales.

Source for these results: [1].

5. Applications

Asymptotic theory is used when the dominant behaviour of a quantity matters more than an exact formula. Main terms describe the leading scale, while error terms determine whether the approximation is reliable in the range being studied.

1. **Algorithms.** Asymptotic estimates compare running times as the input grows, even when exact timings depend on hardware.
2. **Approximation and numerics.** Error scales help choose mesh sizes, truncation points, and the number of terms to retain.
3. **Probability and statistics.** Limit laws describe the typical behavior of averages and estimators when the sample becomes large.
4. **Number theory.** Main terms estimate the distribution of primes and the number of solutions, while error terms measure the quality of the estimate.
5. **Differential equations and fluid mechanics.** Different scales separate a thin boundary layer from the slower bulk motion.

6. **Statistical mechanics and quantum theory.** Large-system limits and semiclassical limits replace a huge exact calculation by a controlled leading description.
7. **Accident-count modelling.** Rare-event approximations estimate risks when the number of opportunities is large but each event is unlikely.

Limitations. The theory depends on limits, inequalities, calculus, series, complex analysis, probability, and linear algebra. Its limitation is not that it is inaccurate; it is that it is deliberately about a limit. A hidden constant may be enormous, convergence may be slow, and a small error in one variable may be amplified by a later operation. Big- O alone does not give a numerical error bound. It also cannot replace a finite-sample calculation when the sample or parameter is not in the asymptotic regime.

6. Connections

Using existing theories

1. Limits and calculus identify the dominant scale as a variable becomes large or small.
2. Series and complex analysis then expose correction terms, while probability and statistics provide the language for typical rather than exact behavior.
3. For example, Stirling's formula replaces $n!$ by $\sqrt{2\pi n}(n/e)^n$ because the logarithm of the factorial is a sum whose leading area is an integral; the correction terms quantify what the leading scale misses [1, 4].

Helping other theories

1. Asymptotic estimates help algorithms predict running time, help numerical methods choose a mesh size, and help differential equations describe boundary layers where one scale changes rapidly.
2. In number theory, the main term describes the average distribution of primes while the error term measures the quality of the information.

3. In physics, an expansion can be useful even when it is not convergent, provided it is stopped before its terms begin to grow [1, 2].

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

1. **Exercise 1.** Prove that $n^2 + 3n \sim n^2$.

Solution. Divide by n^2 : $(n^2 + 3n)/n^2 = 1 + 3/n$, which tends to 1 as $n \rightarrow \infty$.

2. **Exercise 2.** Show that $n \log n = o(n^2)$.

Solution. The ratio is $(n \log n)/n^2 = (\log n)/n$, which tends to zero by l'Hôpital's rule or standard growth comparisons.

3. **Exercise 3.** Explain why $f(n) = O(n^2)$ does not mean $f(n) \sim n^2$.

Solution. The function $f(n) = n$ is $O(n^2)$ but $f(n)/n^2 \rightarrow 0$, not 1. Big- O is only an eventual upper bound; asymptotic equivalence requires ratio 1.

4. **Exercise 4.** Use Stirling's formula to estimate $10!$.

Solution. The leading approximation is $\sqrt{20\pi}(10/e)^{10}$, about 3.60×10^6 , close to the exact value 3,628,800. Correction terms improve it.

5. **Exercise 5.** Why can adding terms to a divergent asymptotic expansion make an answer worse?

Solution. Early terms decrease and improve the approximation, but after the smallest term the divergent coefficients grow. The useful approximation is obtained by truncating near the least term, not by summing indefinitely.

Chapter 6

Automata theory

1. Overview

Intuitive

The problem Whenever a rule must be followed one symbol, event, or moment at a time, we can ask whether a small machine can keep track of what matters. A door lock checks a code, a compiler checks a program, a communication protocol checks the order of messages, and a robot controller responds to sensor readings. Automata theory gives a common language for these situations. It replaces the physical machine by a precisely described model, then proves what that model can and cannot remember.

The word *automaton* means a self-moving or self-acting device. In mathematics it means an ideal machine whose next action is determined by its present state and its current input. The machine may be tiny, or it may have an unbounded tape. The point is not that a real computer looks exactly like the model. The point is that the model isolates memory, choice, and time so that these can be studied separately.

Formal

A deterministic finite automaton is a tuple $(Q, \Sigma, \delta, q_0, F)$: Q is a finite set of states, Σ an input alphabet, $\delta : Q \times \Sigma \rightarrow Q$ the transition function, q_0 the initial state, and F the accepting states. Reading a word follows δ one symbol at a time; the accepted language consists of the words whose final state lies in F . Other machines change the available memory, which changes the class of languages they can

recognize.

2. History

Historical development

1. What problem does the theory solve?

The central problem is recognition. Given a finite string of symbols, should it be accepted as legal? The symbols might be letters in a word, tokens in a computer program, bits in a message, or events in a safety protocol. A second problem is computation: if the machine is allowed to produce outputs, what transformation does it perform? A third is classification: which tasks can be solved with a given amount and kind of memory?

This classification is valuable because it prevents wasted effort. If a language can be recognized by a finite automaton, a small and fast implementation is possible. If it cannot, no clever rearrangement of a finite-state design will solve the problem; the design needs a stack, a queue, a tape, or another source of memory. The theory therefore explains both successful designs and impossibility results [1, 2].

Automata theory developed in the middle of the twentieth century from systems theory, mathematical logic, abstract algebra, and the study of computation. Earlier systems theory often used differential equations to describe physical processes. Automata theorists instead used algebraic structures and discrete steps to describe information systems. Finite-state transducers, Turing machines, pushdown automata, and other models were developed by different communities and later brought together.

The 1956 collection *Automata Studies* helped establish the subject as a separate discipline. Work associated with Claude Shannon, W. Ross Ashby, John von Neumann, Marvin Minsky, Edward Moore, and Stephen Kleene connected automata with information, cybernetics, circuits, and regular languages. In the same period Noam Chomsky described a hierarchy connecting formal grammars with machine power. Rabin and Scott proved that nondeterministic finite automata do not recognize more finite-word languages than deterministic finite automata. Myhill and Nerode gave an exact

test for regularity and a way to count the states in the smallest finite automaton [1, 3].

The researchers were asking a foundational question: when we say that a process is mechanical, how much memory and what kind of choice does it need? That question later became central to compiler construction, complexity theory, artificial intelligence, and formal verification.

3. Theory

Core theory

Figure 6.1: A finite state records only the information needed for the next transition.

The basic machine An automaton receives symbols in discrete steps. The allowed symbols form an input alphabet, denoted by Σ . A finite sequence of symbols is a word; the set of all finite words, including the empty word, is written Σ^* . The machine has states. A state is a compact record of the past that the machine has decided is relevant.

At each step, a transition rule receives the current state and the next input symbol and specifies the next state. A machine that also reports a symbol has an output alphabet Γ and an output rule. One general description is the quintuple

$$M = (\Sigma, \Gamma, Q, \delta, \lambda),$$

where Σ is the input alphabet, Γ the output alphabet, Q the set of states, $\delta : Q \times \Sigma \rightarrow Q$ the next-state rule, and $\lambda : Q \times \Sigma \rightarrow \Gamma$ the output rule. If Q is finite, the machine is a finite automaton.

For language recognition, we normally replace the output rule by a designated start state q_0 and a set F of accepting states. A run on

$a_1 a_2 \dots a_n$ is the state sequence $q_0, q_1, \dots, q_n$ satisfying

$$q_i = \delta(q_{i-1}, a_i).$$

The transition rule extends to whole words by

$$\bar{\delta}(q, \varepsilon) = q, \quad \bar{\delta}(q, wa) = \delta(\bar{\delta}(q, w), a).$$

The word is accepted exactly when $\bar{\delta}(q_0, w)$ lies in F . The language recognized by the machine is

$$L = \{w \in \Sigma^* : \bar{\delta}(q_0, w) \in F\}.$$

Thus an automaton is a finite description that may recognize an infinite set of words [1, 4].

A worked example: even numbers of 1s Take $\Sigma = \{0, 1\}$. Use two states: E means that the number of 1s read so far is even, and O means that it is odd. Start in E and accept E . Reading 0 changes nothing. Reading 1 switches E and O . The word 10110 visits

$$E \longrightarrow O \longrightarrow E \longrightarrow O \longrightarrow E \longrightarrow E,$$

so it is accepted: it contains four 1s. The machine never needs to know the whole word; it only needs the parity of the count. This is the central design principle of finite automata: store exactly the summary that determines every possible future answer.

Finite automata and regular languages A deterministic finite automaton (DFA) has exactly one next state for every current state and input symbol. A nondeterministic finite automaton (NFA) may have several possible next states, including choices made without consuming an input symbol in common definitions. An NFA accepts when at least one allowed run reaches an accepting state. Nondeterminism is a convenient description language, not extra power for finite-word recognition: every NFA can be converted into a DFA by letting a DFA state represent the set of NFA states that could currently be active. This is the subset construction.

The languages recognized by finite automata are the *regular languages*. They can equivalently be described by regular expressions and by regular grammars. This equivalence is one form of Kleene's theorem. It explains why a pattern such as

$$(0 + 1)^* 01$$

can be used by a text-search program: it is a compact notation for a finite machine that searches for a final 01.

Regular languages are closed under union, intersection, complement, concatenation, and repetition. Closure means that after combining two regular descriptions in one of these ways, the result is still regular. Product constructions prove union and intersection; complement is obtained by exchanging accepting and non-accepting states in a complete DFA; concatenation and repetition can be handled with NFAs.

Two proof tools show where finite memory stops being enough. The pumping lemma says that a sufficiently long word in a regular language contains a middle part that can be repeated any number of times while remaining in the language. It is useful for proving that languages such as $\{0^n 1^n : n \geq 0\}$ are not regular. The Myhill–Nerode theorem is stronger and more exact: a language is regular precisely when it has only finitely many distinguishable prefixes, and the number of equivalence classes is the number of states in its minimal DFA. Two prefixes are distinguishable when some continuation is accepted after one prefix but rejected after the other [1, 3].

Memory changes the class of problems Finite-state machines have bounded memory. A pushdown automaton adds a stack. It can push a symbol when it sees an opening bracket and pop one when it sees the matching closing bracket. Since the stack grows with the input, it can recognize balanced parentheses and the language $\{0^n 1^n : n \geq 0\}$. Nondeterministic pushdown automata recognize the context-free languages, the class described by context-free grammars. Deterministic pushdown automata recognize a proper subclass: not every context-free language has a deterministic parser.

A queue machine stores symbols first-in, first-out and is Turing-complete. A Turing machine uses a tape, a read–write head, and a finite instruction table. It can move in both directions and use the tape as unbounded working memory. A linear bounded automaton has a tape whose usable portion is bounded by the input length and is associated with context-sensitive languages. Turing machines recognize the recursively enumerable languages when acceptance may occur but rejection may continue forever. This distinction leads to undecidable problems, such as the halting problem.

The hierarchy is not simply a ladder of faster machines. It is a

hierarchy of the kinds of languages that can be recognized:

finite automata: regular languages
 $\subset$ pushdown automata: context-free languages
 $\subset$ linear bounded automata: context-sensitive languages
 $\subset$ Turing machines: recursively enumerable languages.

Two pushdown stores can simulate a Turing tape, so machines that look only slightly different can have radically different power. Deterministic and nondeterministic Turing machines have the same computability power, although complexity theory studies how much time or space their simulations require [2, 5].

4. Important theorems and results

1. **Kleene's theorem.** A language is regular exactly when it can be described by a regular expression, recognized by a finite automaton, or generated by a regular grammar. This gives three equivalent ways to design the same finite-memory process.
2. **DFA–NFA equivalence.** Every nondeterministic finite automaton has an equivalent deterministic finite automaton. The deterministic machine may have more states, because it records sets of possible NFA states, but it accepts exactly the same words.
3. **Myhill–Nerode theorem.** A language is regular exactly when its prefixes fall into finitely many classes that no continuation can distinguish. The number of classes is the number of states in the minimal DFA. This is both a regularity test and a minimization theorem.
4. **Pumping lemma.** Every sufficiently long word in a regular language has a repeatable middle part. The lemma proves non-regularity when repeating any possible middle part eventually breaks the language rule.
5. **Chomsky hierarchy.** Regular, context-free, context-sensitive, and recursively enumerable languages correspond, in broad terms, to finite automata, pushdown automata, linear bounded automata, and Turing machines. The hierarchy explains why adding memory enlarges the class of recognizable problems.

6. **Church–Turing thesis.** Every effectively calculable step-by-step function can be computed by a Turing machine. This is a foundational claim about the meaning of "algorithm," not a theorem proved from a definition of ordinary calculation.

Source for these results: [1].

5. Applications

Automata theory turns repeated rule-based behaviour into a finite state model whenever the required memory can be represented by states and transitions. This makes recognition, parsing, reachability, and verification precise and testable.

1. **Compilers.** A finite automaton breaks a character stream into tokens such as identifiers, numbers, and keywords. A parser then uses a grammar or a pushdown-style method to check the nested structure of an expression. Finite memory is enough for local spelling rules, whereas nested parentheses require a stack.
2. **Text processing and hardware.** Regular expressions are compiled into finite automata, so a search for a date, an email-like pattern, or a forbidden word becomes a controlled walk through states. A traffic-light controller can be represented by states, and verification can prove that a red light is never followed immediately by a conflicting green light.
3. **Language and cellular models.** Context-free grammars model pieces of human language and have been used in artificial intelligence and natural-language processing. Cellular automata model local updates; Conway's Game of Life shows how simple rules can produce moving patterns, growth, and computation.
4. **Algebra and number theory.** Certain sets of irreducible polynomials over finite fields form regular languages under repeated composition. Automata can also infer a regular language from examples. These applications work because the automaton gives a finite, testable representation of an otherwise potentially infinite family [1, 7].

Limitations. The subject depends on sets, functions, relations, induction, graphs, logic, and basic algebra. A finite automaton cannot

recognize patterns that require unbounded memory, such as arbitrarily balanced parentheses; a pushdown automaton or a stronger model is then required. The choice of states and transitions must therefore match the memory and verification question being asked.

6. Connections

Using existing theories

1. Sets and functions define states and transitions; graphs draw those transitions; formal languages specify which strings are legal.
2. Logic then states properties of every possible run, and algebra can compress the transition behavior into a finite transformation structure.
3. For example, a finite automaton checking a binary number divisible by 3 needs only three states, one for each possible remainder, because reading a digit updates the remainder by a fixed rule [1, 2].

Helping other theories

1. Automata theory helps a compiler turn source text into a syntax tree by recognizing tokens and grammatical structure.
2. The same transition model checks whether every state of a protocol avoids a forbidden condition, which is the basis of model checking and formal verification.
3. In digital circuits and cellular automata, the state-update rule is literally an automaton transition, so questions about long computations become questions about reachable states and accepted languages [4, 6].

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

1. **Exercise 1.** Build a DFA over $\{0, 1\}$ that accepts exactly the words with an even number of 1s.

Solution. Use states E and O , start at E , and accept E . On input 0, both states loop. On input 1, use $E \rightarrow O$ and $O \rightarrow E$. An induction on word length proves that the current state records the parity of the number of 1s.

2. **Exercise 2.** Is $L = \{0^n 1^n : n \geq 0\}$ regular?

Solution. No. If L were regular, the pumping lemma would give a pumping length p . The word $0^p 1^p$ would split as xyz with $|xy| \leq p$ and $|y| > 0$, so y consists only of 0s. Pumping y changes the number of 0s but not the number of 1s, producing a word outside L , a contradiction.

3. **Exercise 3.** Convert the NFA for words ending in 01 into a DFA.

Solution. Let the NFA remember whether it has seen no useful suffix, a possible final 0, or the final 01; the NFA may also keep its start possibility alive while scanning. The DFA states are the subsets of these NFA states. Remove unreachable subsets, and mark every subset containing the NFA accepting state. This subset construction preserves acceptance because it records exactly all positions at which the NFA could be.

4. **Exercise 4.** Explain why a pushdown automaton recognizes balanced parentheses.

Solution. On each opening parenthesis push a marker. On each closing parenthesis pop one marker; reject if the stack is empty. Accept after the input ends only when the stack is empty. The stack records every opening parenthesis not yet matched, so the machine accepts exactly properly nested strings.

5. **Exercise 5.** What is the difference between recognizing and deciding a language with a Turing machine?

Solution. A recognizer halts and accepts words in the language, but may run forever on words outside it. A decider halts on every word and accepts exactly the words in the language. The halting problem is recognizable in a suitable encoding but not decidable.

Further study Start with sets, functions, induction, graphs, and simple logical statements. Then practice drawing finite automata

before learning formal definitions. The natural sequence is regular expressions and DFAs, NFAs and minimization, regular-language proofs, context-free grammars and pushdown automata, Turing machines, decidability, and complexity. Sipser is a readable first university text; Hopcroft, Motwani, and Ullman give a traditional treatment; Eilenberg and Arbib develop algebraic and structural viewpoints.

Chapter 7

Bass–Serre theory

1. Overview

Intuitive

The problem A group can be difficult to understand when its elements are presented by many relations. Bass–Serre theory gives a geometric picture: make the group act on a tree, a connected graph with no loops. Vertices and edges then carry subgroups, and the way those subgroups are attached records whether the group is a free product, an amalgamated product, or an HNN extension.

Formal

Let a group G act without inversions on a tree T . Each vertex v and edge e has a stabilizer subgroup G_v or G_e . The quotient graph $G\backslash T$, together with these stabilizers and the inclusion maps from edge groups to vertex groups, is a graph of groups. Bass–Serre theory reconstructs G as the fundamental group of this graph of groups and uses the action on T to study its structure.

2. History

Historical development

1. History and motivation.

Jean-Pierre Serre developed the theory in the 1970s, with Hyman Bass making major contributions to its formalization. Serre’s book

Trees grew partly from the study of algebraic groups whose Bruhat–Tits buildings are trees. The method quickly became central to geometric group theory and three-manifold topology.

The older algebraic constructions were free products with amalgamation and HNN extensions. Bass–Serre theory did not replace them; it explained them geometrically through covering spaces, fundamental groups, and group actions. A graph of groups is a one-dimensional analogue of an orbifold: groups sit at vertices and edges, and inclusions describe how local symmetry is glued into global symmetry [1, 3].

3. Theory

Core theory

Trees and group actions A tree is a graph in which any two vertices are joined by exactly one simple path. Let a group G act on a tree X by graph automorphisms. The stabilizer of a vertex v is

$$G_v = \{g \in G : gv = v\},$$

and the stabilizer of an edge e is defined similarly. We assume first that there are no edge inversions: no element flips an edge while fixing its midpoint.

The quotient graph X/G records the orbits of vertices and edges. The quotient alone loses information, so attach the vertex stabilizer to each quotient vertex and the edge stabilizer to each quotient edge. The inclusion of an edge stabilizer into the stabilizer of its endpoint gives the attaching maps. The result is a graph of groups.

The action is geometric information about G . If G acts freely on a tree, no nonidentity element fixes a vertex, and the quotient graph has fundamental group isomorphic to G . This immediately implies that a group acting freely on a tree is free.

Graphs of groups and their fundamental group Choose a maximal subtree T in the underlying graph of a graph of groups $\mathcal{A}$. The fundamental group is generated by all vertex groups and one stable letter for each edge outside T , subject to the internal relations in every vertex group, the relations identifying the two images of each edge-group element along an edge in T , and conjugacy relations involving the stable letters for edges outside T .

If the graph has two vertices joined by one edge, with vertex groups A and B and edge group C embedded in each, the fundamental group is the amalgamated product

$$A *_C B.$$

If the graph has one vertex and one loop edge with edge group C embedded twice in A , the fundamental group is an HNN extension

$$\langle A, t \mid t^{-1}\alpha(c)t = \beta(c) \text{ for } c \in C \rangle.$$

Free products are the special case C trivial.

Bass–Serre covering trees Every graph of groups $\mathcal{A}$ with a chosen base vertex has a canonical covering tree $\tilde{\mathcal{A}}$. Its vertices can be represented by cosets of vertex groups in the fundamental group, and its edges by cosets of edge groups. The fundamental group acts on this tree without edge inversions. The quotient graph of groups is the original $\mathcal{A}$.

Conversely, if G acts on a tree X without inversions, the quotient graph of groups has a covering tree naturally isomorphic to X . The construction generalizes the universal cover of an ordinary graph. Ordinary covering theory has a fundamental group acting on a tree; Bass–Serre theory allows nontrivial stabilizers, so the local groups become part of the cover.

The fundamental theorem Let G act on a tree X without inversions, let $\mathcal{A}$ be the quotient graph of groups, and choose a base vertex v . Then

$$G \cong \pi_1(\mathcal{A}, v),$$

and X is equivariantly isomorphic to the Bass–Serre covering tree of $\mathcal{A}$. The isomorphisms respect both the group action and the graph structure.

This theorem is powerful in both directions. To understand an action, pass to the quotient graph of groups and obtain a group decomposition. To build an action for a group given by an amalgam or HNN extension, build its Bass–Serre tree.

Basic consequences If a graph of groups has a spanning tree and fundamental group G , the natural maps from its vertex groups into G

are injective. A finite-order element of G is conjugate to an element of a vertex group. More generally, every finite subgroup is conjugate into some vertex group. If the quotient graph is finite and all vertex groups are finite, G is virtually free: it contains a free subgroup of finite index.

Finite graphs of finitely generated vertex groups give finitely generated fundamental groups. If vertex groups are finitely presented and edge groups finitely generated, the resulting group is finitely presented. These statements make a decomposition useful for transferring finiteness properties from local groups to the global group.

Trivial and nontrivial actions An action is trivial if the whole group fixes a vertex. A graph of groups is correspondingly trivial when its underlying graph is a tree and the edge inclusions collapse the other vertex groups into the chosen base vertex group. Such a decomposition does not reveal a genuine splitting.

Nontrivial actions have no global fixed vertex and encode a real group splitting. The distinction matters in applications: rooted-tree actions may be interesting even when they fix a root, but Bass–Serre decomposition arguments generally seek actions that cannot be reduced to one vertex group.

Ends, property T, and accessibility Stallings’ theorem says that a finitely generated group has more than one end exactly when it admits a nontrivial splitting over a finite subgroup. In Bass–Serre language, the group acts nontrivially on a tree with finite edge stabilizers. This turns a coarse geometric property of the Cayley graph into an algebraic decomposition.

If a group has Kazhdan’s property (T), every action on a tree without inversions has a global fixed vertex. Such a group has Serre’s property FA and cannot split nontrivially in the Bass–Serre sense. This provides an obstruction to decomposition.

Accessibility theorems bound the complexity of splittings. Dunwoody proved that a finitely presented group has a bound on the number of edges in reduced splittings over finite subgroups. Bestvina and Feighn generalized accessibility to splittings over small subgroups. These results say that decomposition cannot continue indefinitely once finiteness hypotheses are imposed [4, 5].

4. Important theorems and results

1. **Fundamental theorem of Bass–Serre theory.** A group acting without inversions on a tree is the fundamental group of its quotient graph of groups, and the tree is the associated Bass–Serre covering tree.
2. **Free-action theorem.** A group acting freely on a tree is a free group.
3. **Kurosh subgroup theorem.** Subgroups of a free product decompose as a free product of conjugates of subgroups of the factors together with a free group.
4. **Stallings’ ends theorem.** A finitely generated group has more than one end exactly when it splits nontrivially over a finite subgroup.
5. **Property FA consequence.** A group with Kazhdan’s property (T) fixes a vertex in every tree action without inversions and therefore has no nontrivial Bass–Serre splitting.
6. **Accessibility.** Under suitable finite-presentation assumptions, the complexity of reduced splittings is bounded.

Source for these results: [1].

5. Applications

Bass–Serre theory applies group actions on trees to groups assembled from simpler pieces. The resulting tree records free products, amalgamations, and HNN extensions in a form that exposes their subgroup structure.

1. **Free product.** The group $A * B$ acts on a tree whose vertices are cosets of A and B and whose edges connect compatible cosets. The quotient is one edge with two vertices and trivial edge group. The tree makes reduced words alternate between factors.
2. **Amalgamated product.** If two groups share a subgroup C , the group $A *_C B$ glues the two vertex groups along C . The edge stabilizer records exactly the elements identified in the gluing. This appears in three-manifold groups and combination theorems.

3. **HNN extension.** An HNN extension joins two copies of a subgroup inside one group with a stable letter. The Bass–Serre tree records repeated conjugation of one subgroup into another. It is a natural model for groups built by adding a symmetry that identifies two substructures.
4. **Three-manifolds and geometry.** Splittings over boundary or torus subgroups help analyze fundamental groups of three-manifolds. The tree records how pieces are assembled and interacts with geometric decompositions.
5. **Geometric group theory.** Actions on trees are one-dimensional models of nonpositive-curvature actions. They help study subgroup structure, free subgroups, ends, and algorithmic questions about group presentations.

6. Connections

Using existing theories

1. Group theory supplies the symmetries, graph theory supplies vertices and edges, and topology explains why a graph of groups behaves like a space assembled from pieces.
2. The fundamental group of a graph records the possible ways to travel around it; when groups are attached to vertices and edge groups describe the overlaps, the resulting action on a tree records how the whole group splits.
3. An amalgamated product identifies a shared subgroup, while an HNN extension identifies two copies of one subgroup [1, 2].

Helping other theories

1. The action on a tree turns an algebraic splitting into geometry: vertex stabilizers are the pieces, edge stabilizers are the overlaps, and the quotient graph displays the assembly plan.
2. This makes free products and subgroup structure visible, gives criteria for decomposing fundamental groups of three-manifolds, and supplies geometric tools for studying groups that are too large to classify by generators and relations alone [1, 4].

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

1. **Exercise 1.** Why is a group acting freely on a tree free?

Solution. The quotient of the tree by the free action is a graph with the group as its group of deck transformations. The fundamental group of a graph is free, and the deck group is isomorphic to that fundamental group.

2. **Exercise 2.** What is the graph of groups for $A * B$?

Solution. It has two vertices labelled A and B , one edge labelled by the trivial group, and the trivial inclusions into both vertex groups.

3. **Exercise 3.** What does an edge stabilizer represent?

Solution. It is the subgroup fixing the edge. In the quotient graph of groups it is embedded into the stabilizers of both endpoint vertices, recording the subgroup along which the local groups are glued.

4. **Exercise 4.** What is the difference between an amalgamated product and an HNN extension?

Solution. An amalgamated product joins two vertex groups along a common subgroup. An HNN extension uses one vertex group and a stable letter to identify two embedded copies of a subgroup inside it.

5. **Exercise 5.** What does Stallings' theorem say geometrically?

Solution. More than one end means that the Cayley graph has several infinite directions after deleting a finite region. Bass–Serre theory says this happens exactly when the group acts nontrivially on a tree with finite edge stabilizers.

Chapter 8

Bifurcation theory

1. Overview

Intuitive

The problem A parameter can change smoothly while the behavior of a system changes suddenly. A population may remain near zero and then settle at a positive level; a circuit may begin to oscillate; a fluid flow may lose stability and develop a new pattern. Bifurcation theory locates and classifies the parameter values at which the qualitative structure of solutions changes.

Formal

For an equation $F(x, \lambda) = 0$, a bifurcation is a parameter value λ_0 at which the nearby solution set changes qualitatively. At an equilibrium, the linearization $D_x F$ determines local behavior; loss of invertibility, together with suitable nondegeneracy conditions, signals a possible branch or stability change. Normal-form calculations reduce the local behavior to a simpler equation while preserving the relevant qualitative features.

2. History

Historical development

1. History and motivation.

The word bifurcation was introduced by Henri Poincaré in 1885 while studying changes in equilibria and periodic solutions of differential equations. Later work by Andronov, Hopf, Arnold, Smale, and many others developed local normal forms and global dynamical methods. The researchers were trying to understand why a small change in a physical parameter could change the number or stability of solutions, something a single solution formula could not reveal.

Bifurcation theory applies to continuous systems such as ordinary, delay, and partial differential equations, and to discrete systems such as iterated maps. It is closely related to dynamical systems, chaos, catastrophe theory, control, and nonlinear analysis [1, 3].

3. Theory

Core theory

Figure 8.1: A bifurcation diagram records how long-term behavior changes with a parameter.

Equilibria, stability, and a changing parameter Consider

$$\dot{x} = f(x, \lambda),$$

where λ is a parameter. An equilibrium x_* satisfies $f(x_*, \lambda) = 0$. To test its local stability, linearize:

$$\dot{u} = D_x f(x_*, \lambda)u.$$

If all eigenvalues have negative real part, small disturbances decay; if one has positive real part, the equilibrium is unstable. At a bifurcation, a stability eigenvalue reaches the boundary: in continuous time its

real part is zero, while for a discrete map $x_{n+1} = f(x_n, \lambda)$ a multiplier has modulus one.

The scalar example

$$\dot{x} = rx - x^3$$

has $x = 0$ for all r . When $r < 0$, the derivative at zero is $r < 0$, so zero is stable. When $r > 0$, zero is unstable and two new equilibria $x = \pm\sqrt{r}$ appear; their derivative is $r - 3r = -2r < 0$, so they are stable. The phase portrait changes at $r = 0$. This is a supercritical pitchfork in a symmetric system.

Local bifurcations A local bifurcation can be understood in an arbitrarily small neighborhood of the changing equilibrium or periodic orbit. The implicit-function theorem explains why a smooth branch of equilibria persists when the derivative with respect to x is invertible. Failure of this condition is the signal that a branch can turn, cross, or split.

Saddle-node. The normal form

$$\dot{x} = \lambda - x^2$$

has two equilibria for $\lambda > 0$, one double equilibrium at $\lambda = 0$, and no equilibria for $\lambda < 0$. A stable and an unstable equilibrium are created or destroyed together.

Transcritical. In

$$\dot{x} = \lambda x - x^2,$$

the branches $x = 0$ and $x = \lambda$ cross and exchange stability. This often describes a threshold between two competing states.

Pitchfork. In the symmetric example above, one equilibrium becomes unstable and two symmetric equilibria appear. Symmetry is important: without a symmetry or constraint, a pitchfork usually unfolds into other bifurcations.

Hopf. A pair of complex-conjugate eigenvalues crosses the imaginary axis. An equilibrium changes stability and a small periodic orbit is born or disappears. Hopf bifurcation explains the onset of oscillations in chemical reactions, biological rhythms, lasers, and electrical circuits.

For maps, the corresponding conditions use multipliers. A multiplier $+1$ may lead to a saddle-node, transcritical, or pitchfork; a multiplier -1 often produces period doubling. A pair on the unit circle can generate a discrete analogue of Hopf behavior.

Codimension The codimension is the number of independent parameters that must be adjusted to produce a generic bifurcation. Saddle-node and Hopf bifurcations are generically codimension one: varying one parameter is usually enough. Transcritical and pitchfork normal forms are also drawn with one parameter, although symmetry or another condition may be needed for them to occur robustly.

The Bogdanov–Takens bifurcation is a standard codimension-two example. Two conditions must be met, often producing nearby saddle-node, Hopf, and homoclinic curves in a two-parameter diagram. Codimension counts how many coincidences must be arranged, not how visually complicated the resulting dynamics will be.

Global bifurcations Global bifurcations cannot be detected from the eigenvalues of one equilibrium. They involve large invariant sets colliding or changing topology.

Homoclinic bifurcation. A periodic orbit may collide with a saddle point and its stable and unstable manifolds. The period can grow very large near the collision, and complicated or chaotic behavior may appear.

Heteroclinic bifurcation. A cycle of connections among two or more saddle points changes stability. Resonance conditions on eigenvalues can create or destroy periodic orbits; transverse intersections can alter the global connection.

Infinite-period bifurcation. A stable node and a saddle can be created on a limit cycle while the oscillation slows and its period tends to infinity. Beyond the threshold, the cycle disappears and the equilibria remain.

Blue-sky catastrophe and crises. A periodic orbit can collide with a nonhyperbolic invariant cycle, or a chaotic attractor can collide with a basin boundary. These events can cause a sudden enlargement or destruction of the observed attractor.

The local/global distinction is practical. Linearization is powerful near an equilibrium, but it cannot reveal that a distant periodic orbit will collide with a saddle.

Bifurcation diagrams and normal forms A bifurcation diagram plots equilibria or periodic-orbit amplitudes against the parameter. Solid and dashed curves often indicate stable and unstable branches. A normal form is a simplified equation obtained by coordinate changes

and scaling that preserves the behavior relevant near the bifurcation. It removes terms that do not affect the leading qualitative change.

Center-manifold reduction explains why a high-dimensional system can often be reduced to a one- or two-dimensional equation near a nonhyperbolic equilibrium. The center manifold contains the slow directions associated with zero-real-part eigenvalues; stable directions decay and can be slaved to them. Normal-form calculations then classify the possible local behavior.

4. Important theorems and results

1. **Implicit-function theorem.** If the derivative with respect to the state is invertible, a nearby solution branch continues smoothly with the parameter. Bifurcation requires failure of this regularity condition.
2. **Linear stability criterion.** Eigenvalues with negative real parts give local decay in continuous time; a positive real part gives instability. For maps, stability corresponds to multipliers inside the unit circle.
3. **Center-manifold theorem.** Near a nonhyperbolic equilibrium, the local dynamics relevant to bifurcation can be reduced to a center manifold of lower dimension.
4. **Hopf bifurcation theorem.** Under nondegeneracy and transversality conditions, a pair of eigenvalues crossing the imaginary axis produces a branch of small periodic orbits.
5. **Saddle-node normal form.** The equation $\dot{x} = \lambda - x^2$ captures the generic creation or destruction of an equilibrium pair.
6. **Bogdanov–Takens unfolding.** A codimension-two double-zero eigenvalue organizes nearby saddle-node, Hopf, and homoclinic bifurcation curves.

Source for these results: [1].

5. Applications

Bifurcation theory is useful when changing a parameter changes the number, stability, or type of solutions of a differential equation. The

critical parameter identifies where a qualitative transition occurs.

1. **Population dynamics.** A harvesting or reproduction parameter can create a stable positive population through a transcritical or saddle-node event. A small change past the threshold may remove the only sustainable equilibrium.
2. **Chemical and biological oscillators.** Feedback in a reaction network can cause a Hopf bifurcation. As a control parameter crosses the threshold, a stable equilibrium gives way to a stable periodic concentration cycle. Cell-cycle switches and biochemical networks use bistable and irreversible switches whose output changes near a bifurcation point.
3. **Fluid mechanics and climate.** Increasing the Reynolds number can destabilize a steady flow and create vortices or periodic shedding. Climate models may have multiple equilibria, with transitions between them organized by saddle-node or global bifurcations.
4. **Lasers, circuits, and quantum systems.** Laser intensity can emerge through a threshold bifurcation, and electronic feedback circuits can begin to oscillate at a Hopf point. In atomic and molecular systems, bifurcations of classical orbits leave enhanced signatures in quantum spectra. Resonant tunnelling diodes, kicked tops, and coupled quantum wells provide model examples.
5. **Engineering and control.** Bifurcation diagrams show where a controller will lose stability or where a desired operating state disappears. Continuation methods follow solution branches numerically and reveal turning points that ordinary simulation might miss [2, 4].

6. Connections

Using existing theories

1. Calculus linearizes a differential equation near an equilibrium, and linear algebra turns that linearization into eigenvalues that indicate growth, decay, or oscillation.
2. Dynamical systems and phase portraits then follow the nearby trajectories, while topology explains why branches of equilibria cannot simply disappear without a change in the equations.

3. Numerical continuation traces those branches as a parameter changes, so a bifurcation is detected as a structural change rather than as one surprising numerical output [1, 2].

Helping other theories

1. Bifurcation theory tells control engineers where a stable operating point will become unstable and tells biologists where a population equilibrium can split into several regimes.
2. In climate and fluid models, a parameter crossing a threshold can create oscillations or multiple states; in laser models it can turn a zero signal into a sustained one.
3. Chaos theory often begins after repeated bifurcations, while catastrophe theory classifies the local shapes of the resulting transitions [1, 4].

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

1. **Exercise 1.** Analyze the equilibria of $\dot{x} = rx - x^3$.

Solution. Equilibria are $x = 0$ and, for $r \geq 0$, $x = \pm\sqrt{r}$. The derivative is $r - 3x^2$. Thus zero is stable for $r < 0$ and unstable for $r > 0$, while the two nonzero branches are stable for $r > 0$. This is a supercritical pitchfork.

2. **Exercise 2.** Classify the equilibria of $\dot{x} = \lambda - x^2$.

Solution. For $\lambda > 0$, $x = \pm\sqrt{\lambda}$; the positive branch has derivative $-2\sqrt{\lambda} < 0$ and is stable, the negative branch unstable. At $\lambda = 0$ they merge, and for $\lambda < 0$ there are none: a saddle-node.

3. **Exercise 3.** What eigenvalue condition signals a local continuous-time bifurcation?

Solution. At least one eigenvalue of the Jacobian has real part zero. A zero eigenvalue gives a steady-state bifurcation; a nonzero

purely imaginary pair gives the linear signal for a Hopf bifurcation. Nondegeneracy conditions are still required.

4. **Exercise 4.** Why is a homoclinic bifurcation global?

Solution. It involves an entire orbit connecting a saddle to itself and therefore the global stable and unstable manifolds, not just the eigenvalues at the saddle. The change cannot be confined to an arbitrarily small neighborhood.

5. **Exercise 5.** What does codimension two mean for a Bogdanov–Takens point?

Solution. Two independent conditions must be met, so one generally needs two parameters to reach the degenerate point. Nearby parameter values may display several codimension-one curves such as saddle-node and Hopf branches.

Chapter 9

Braid theory

1. Overview

Intuitive

The problem When several strands move from one row of points to another, their over-and-under crossings remember more than the final permutation of the endpoints. Braid theory turns these motions into algebra. Braids can be stacked, undone, represented by generators and relations, closed to make knots, and studied through configuration spaces and mapping classes.

Formal

The braid group B_n is generated by $\sigma_1, \dots, \sigma_{n-1}$, where σ_i crosses strand i over strand $i + 1$. Its defining relations are $\sigma_i \sigma_j = \sigma_j \sigma_i$ when $|i - j| \geq 2$ and $\sigma_i \sigma_{i+1} \sigma_i = \sigma_{i+1} \sigma_i \sigma_{i+1}$. Multiplication is stacking braids, and the map $B_n \rightarrow S_n$ records the permutation of endpoints.

2. History

Historical development

1. History and the basic picture.

Braid groups were introduced explicitly by Emil Artin in 1925, although Adolf Hurwitz had already encountered their configuration-space meaning in work on monodromy. Artin's 1947 presentation made the groups accessible through generators and relations. Joan

Figure 9.1: A braid records the ordered crossings of moving strands; closing it produces a knot or link.

Birman's 1974 book connected braids, links, and mapping class groups and became a central reference.

Take n points in a row and connect them to another row. Each strand moves monotonically from left to right. Two diagrams represent the same braid when one can be continuously deformed into the other without strands passing through one another. Over-crossing and under-crossing are part of the data. Stack one braid after another to compose them. Parallel strands give the identity, and reflecting a braid reverses it to give the inverse [1, 4].

3. Theory

Core theory

The braid group and its configuration-space meaning The braid group B_n consists of isotopy classes of braids on n strands. Equivalently, let X be a connected manifold of dimension at least two. The unordered configuration space of n distinct points is

$$\text{Conf}_n(X) = (X^n \setminus \{x_i = x_j \text{ for some } i \neq j\})/S_n.$$

Its fundamental group is the braid group of X . A loop in this configuration space records points moving around one another and returning as an unordered set. If the labels must return to their original positions, the loop lies in the pure braid group.

This interpretation explains why braids compose and why homotopy, rather than a particular drawing, is the correct equivalence relation. For the plane, it gives the classical Artin braid group. In some cases the higher homotopy groups of the configuration space are trivial, making the braid group the main topological information.

Generators and relations Let σ_i be the braid in which strand i crosses over strand $i+1$, with all other strands straight. The generators $\sigma_1, \dots, \sigma_{n-1}$ satisfy

$$\sigma_i \sigma_j = \sigma_j \sigma_i \quad \text{when } |i - j| \geq 2,$$

because distant crossings do not interact, and

$$\sigma_i \sigma_{i+1} \sigma_i = \sigma_{i+1} \sigma_i \sigma_{i+1},$$

because the two three-crossing diagrams are isotopic. The group presentation is

$$B_n = \langle \sigma_1, \dots, \sigma_{n-1} \mid \sigma_i \sigma_{i+1} \sigma_i = \sigma_{i+1} \sigma_i \sigma_{i+1}, \sigma_i \sigma_j = \sigma_j \sigma_i \ (|i-j| \geq 2) \rangle.$$

The cubic relation is the braid relation appearing in the Yang–Baxter equation and in Artin groups.

Elementary properties B_1 is trivial and $B_2 \cong \mathbb{Z}$. The group B_3 is infinite and nonabelian and is closely related to the trefoil knot group. Each B_n embeds in B_{n+1} by adding a straight strand, and their increasing union is the infinite braid group B_∞ .

Braid groups are torsion-free. For $n \geq 3$, they contain a free group on two generators and admit a left-invariant Dehornoy order. Sending every σ_i to 1 gives a homomorphism $B_n \rightarrow \mathbb{Z}$ and identifies the abelianization.

Symmetric group and pure braids Forget the over-under information but remember where each strand ends. This gives a surjective homomorphism

$$B_n \longrightarrow S_n, \quad \sigma_i \mapsto (i, i+1).$$

The kernel is the pure braid group P_n , in which each strand returns to its own starting point. Pure braids are the fundamental group of the ordered configuration space. They fit into split exact sequences

$$1 \longrightarrow F_{n-1} \longrightarrow P_n \longrightarrow P_{n-1} \longrightarrow 1,$$

so they can be built as iterated semidirect products of free groups.

Three strands and the modular group The group B_3 has a distinguished central element. Modding out by its center gives the modular group $\mathrm{PSL}(2, \mathbb{Z})$. Thus B_3 is a universal central extension of the modular group in the relevant sense. With

$$a = \sigma_1 \sigma_2 \sigma_1, \quad b = \sigma_1 \sigma_2,$$

the braid relation yields $a^2 = b^3$, and the common value is central. This relationship connects braids to modular forms, mapping classes of the punctured torus, and low-dimensional topology [2, 5].

Closed braids and knots Join corresponding top and bottom endpoints of a braid. The result is a link in three-dimensional space, possibly with one component (a knot) or several components. Alexander's theorem says every link is isotopic to the closure of some braid.

Different braids can have the same closure. Markov's theorem gives the exact moves relating braid representatives of the same link: conjugation and stabilization/destabilization. The Jones polynomial was first defined using braid representations and then shown to depend only on the closed link. The braid index is the smallest number of strands needed to represent a link as a closed braid, and it equals the minimum number of Seifert circles in a projection.

Mapping class groups and classification Braids can be viewed as mapping classes of a disk with marked points. A braid is a homeomorphism of the punctured disk, considered up to isotopy while fixing the boundary. This makes braid theory part of the study of surfaces.

The Nielsen–Thurston classification divides mapping classes into periodic, reducible, and pseudo-Anosov types. Pseudo-Anosov behavior stretches and folds curves at a definite rate; that rate gives a lower bound for topological entropy. The classification is useful in fluid mixing, where moving rods create braid patterns in space-time trajectories.

4. Important theorems and results

1. **Artin presentation.** The braid group is generated by adjacent crossings subject only to far-commutativity and the three-strand braid relations.

2. **Alexander's theorem.** Every link in three-space is isotopic to the closure of a braid.
3. **Markov's theorem.** Two braids have isotopic closures precisely when they are related by conjugation and stabilization or destablization moves.
4. **Configuration-space theorem.** The braid group is the fundamental group of the configuration space of distinct unordered points.
5. **Pure-braid extension.** The kernel of $B_n \rightarrow S_n$ is P_n , and P_n is built from iterated semidirect products of free groups.
6. **Nielsen–Thurston classification.** Mapping classes, including braids, are periodic, reducible, or pseudo-Anosov, with distinct dynamical behavior.

Source for these results: [1].

5. Applications

Braid theory models the motion of distinct strands and records how their crossings compose. The resulting algebra connects configuration spaces with knots, mixing, monodromy, and operators in mathematical physics.

1. **Knot theory.** Closing a braid represents every link. Braid words provide finite data for knot invariants, Markov moves explain when two words describe the same link, and representations lead to polynomial invariants.
2. **Fluid mixing.** Physical rods, periodic orbits, or almost-invariant sets trace braids. The Nielsen–Thurston type and its entropy estimate how efficiently the stirring produces stretching and mixing.
3. **Quantum physics.** In two spatial dimensions, exchanging indistinguishable particles can produce braid-group rather than symmetric-group statistics. Anyons use this possibility, and their braid representations are proposed for fault-tolerant quantum computation.
4. **Algebraic geometry.** Moving roots of a polynomial around one another produces monodromy, represented by a braid. The resulting

braid action records how solutions permute when parameters travel around singular values.

5. **Yang–Baxter equation.** Operators satisfying the braid relation lead to solvable lattice models, quantum groups, and statistical mechanics. The geometric crossing relation becomes an algebraic equation for an operator.

6. Connections

Using existing theories

1. A braid records paths of moving points, so configuration spaces turn physical motion into loops and group theory records how those loops compose.
2. The braid relation says that sliding one crossing past another does not change the final motion; this is a topological fact expressed as an algebraic equation.
3. Closing a braid produces a link, which is why knot theory and mapping class groups appear naturally [1, 3].

Helping other theories

1. The same crossing operations model stirring: repeated braid words describe how fluid filaments are stretched and folded, and their growth can estimate mixing.
2. In quantum information and quantum groups, braid generators act as operators whose relations guarantee that different sequences of pairwise exchanges agree.
3. The closure construction also turns algebraic braid data into knot polynomials and other invariants [2, 4, 5].

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

1. **Exercise 1.** Why do $\sigma_1\sigma_3$ and $\sigma_3\sigma_1$ commute in B_4 ?

Solution. The crossings involve disjoint pairs of strands. They can be performed in either order without changing the isotopy class, so $|1 - 3| \geq 2$ gives the far-commutativity relation.

2. **Exercise 2.** What is the image of $\sigma_1\sigma_2\sigma_1$ in S_3 ?

Solution. It is $(1, 2)(2, 3)(1, 2)$, a permutation obtained by composing adjacent transpositions. The map forgets over-under information but remembers endpoints.

3. **Exercise 3.** What is the pure braid group?

Solution. It is the kernel of $B_n \rightarrow S_n$. A pure braid allows strands to wind around one another but requires each strand to finish at the position where it started.

4. **Exercise 4.** How can a braid become a knot?

Solution. Join each lower endpoint to the corresponding upper endpoint. The resulting closed braid is a link; it is a knot when it has one connected component.

5. **Exercise 5.** Why is the Yang–Baxter equation related to braids?

Solution. The equation says that two different sequences of three pairwise interactions give the same operator. This is exactly the algebraic counterpart of the isotopy $\sigma_i\sigma_{i+1}\sigma_i = \sigma_{i+1}\sigma_i\sigma_{i+1}$.

Chapter 10

Brill–Noether theory

1. Overview

Intuitive

The problem A curve has divisors, and a divisor can support functions or maps to projective space. The surprising question is whether it supports more independent functions than its degree and the curve’s genus seem to allow. Brill–Noether theory studies these special divisors, predicts their dimensions on a generic curve, and identifies when a curve has exceptional geometry.

Formal

Let C be a smooth projective curve of genus g . The Brill–Noether locus is

$$W_d^r(C) = \{L \in \operatorname{Pic}^d(C) : h^0(C, L) \geq r + 1\}.$$

Its expected dimension is governed by $\rho(g, r, d) = g - (r + 1)(g - d + r)$. The theory asks when this locus is nonempty, what its dimension is, and how the answer changes for a special curve.

2. History

Historical development

1. History and the central question.

The theory was introduced by Alexander von Brill and Max Noether in 1874. They studied special divisors on smooth projective curves

and discovered that some divisors move in larger linear systems than a naive count predicts. Modern formulations use line bundles, sheaf cohomology, the Picard variety, and moduli spaces.

Let C be a smooth projective curve of genus g over an algebraically closed field. A divisor D determines a line bundle $\mathcal{O}_C(D)$ and a vector space of sections $H^0(C, \mathcal{O}_C(D))$. Its dimension is written $h^0(D) = r + 1$. A complete linear system of degree d and dimension r is often denoted g_d^r . It gives a map to $\mathbb{P}^r$ when the sections have no common zero [1, 3].

3. Theory

Core theory

Special divisors and Riemann–Roch

Concrete illustration: low-genus examples *Genus 2.* Every genus-2 curve C is hyperelliptic: there exists a degree-2 map $C \rightarrow \mathbb{P}^1$, i.e. a g_2^1 . Take a concrete example, $C: y^2 = x^6 - 1$ over $\mathbb{C}$. A divisor $D = P_1 + P_2$ consisting of two Weierstrass points (points where $x^6 = 1$, $y = 0$) has $\deg D = 2$ and $h^0(D) = 2$, giving a complete g_2^1 . Riemann–Roch yields $h^0(D) - h^1(D) = 2 - 2 + 1 = 1$; since $h^1(D) = h^0(K - D)$ by Serre duality and $\deg K = 2$ for genus 2, when $D \neq K$ we get $h^0(D) = 2$. Now consider a divisor of degree 3: any effective divisor of degree 3 on a genus-2 curve has $h^0(D) \geq 2$ (by Riemann–Roch: $h^0 - h^1 = 3 - 2 + 1 = 2$, and $h^1 \geq 0$), so there is always at least a g_3^1 , and often a g_3^2 .

Genus 3. A general genus-3 curve is a smooth plane quartic in $\mathbb{P}^2$. Its canonical series is a g_4^2 embedding $C \hookrightarrow \mathbb{P}^2$. For a point $P \in C$, the divisor $D = K_C - P$ has degree $2g - 2 - 1 = 3$ and $h^0(D) = g - 1 = 2$ (by Riemann–Roch, since $h^1(D) = h^0(P) = 1$), giving a g_3^1 : a degree-3 map $C \rightarrow \mathbb{P}^1$. The Brill–Noether number for this system is $\rho(3, 1, 3) = 3 - 2(3 - 3 + 1) = -1 < 0$, so a general genus-3 curve does *not* carry a g_3^1 coming from this naive count. However, the computation above shows a g_3^1 always exists (just shift K_C by one point). The point is that ρ is negative for the *specified* type; the actual system exists for geometric reasons but is not “expected.” By contrast, a degree-2 map g_2^1 has $\rho(3, 1, 2) = 3 - 2(3 - 2 + 1) = -1 < 0$ —and indeed a general genus-3 curve has no g_2^1 ; only hyperelliptic genus-3 curves do.

This neatly separates the general locus from the hyperelliptic locus in moduli space.

Riemann–Roch says

$$h^0(D) - h^1(D) = \deg D - g + 1.$$

The term $h^1(D)$ measures the failure of the number of sections to be the ordinary expected value. A divisor is special when $h^1(D) > 0$. By Serre duality, this is equivalent to the existence of a holomorphic differential whose divisor is at least $-D$.

The theory is therefore a refined question about sections. A degree- d divisor may move in a family of dimension greater than expected because the curve has a special shape, an extra symmetry, or a low-degree map to another curve. The same language describes line bundles, maps to projective space, and embeddings.

The Brill–Noether number The Brill–Noether number is

$$\rho(g, r, d) = g - (r + 1)(g - d + r).$$

It is the expected dimension of the space $G_d^r(C)$ of degree- d linear systems with at least $r + 1$ sections. The formula can be remembered from Riemann–Roch:

$$\rho = g - h^0(D)h^1(D)$$

at the expected values.

If $\rho < 0$, a general curve should have no such linear series. If $\rho = 0$, one expects finitely many. If $\rho > 0$, one expects a family of dimension ρ . An exceptional curve may violate the generic expectation by possessing extra series.

Main theorems Kempf proved that when $\rho \geq 0$, $G_d^r(C)$ is nonempty for a smooth curve in the standard range and every component has dimension at least ρ . Fulton and Lazarsfeld proved connectedness when $\rho \geq 1$. Griffiths and Harris showed that for a general curve the space is reduced and has components of exactly dimension ρ , hence is empty when $\rho < 0$. Gieseker proved smoothness for a general curve; connectedness then gives irreducibility when $\rho > 0$.

These results distinguish generic geometry from special geometry. A hyperelliptic curve, for instance, has a degree-two map to $\mathbb{P}^1$ and therefore a linear system that a general curve of the same genus may not have.

Maps and examples A g_d^1 is a pencil of degree d : two independent sections give a map $C \rightarrow \mathbb{P}^1$. A hyperelliptic curve has a g_2^1 . A canonical linear system, associated with holomorphic differentials, maps a nonhyperelliptic curve of genus $g \geq 3$ into $\mathbb{P}^{g-1}$.

For $g = 3$, $r = 1$, and $d = 2$,

$$\rho = 3 - 2(3 - 2 + 1) = -1.$$

Thus a general genus-three curve has no degree-two map to $\mathbb{P}^1$, although hyperelliptic genus-three curves do. The negative expected dimension expresses a generic nonexistence statement rather than an absolute impossibility.

Moduli and the maximal-rank problem The moduli space of genus- g curves contains a dense set of general curves. Brill–Noether theory predicts which linear systems occur on that dense set and how large their parameter spaces are. Degenerate or special curves lie in proper loci and can have more sections.

The maximal rank conjecture concerns a general curve $C \subset \mathbb{P}^r$ embedded by a general linear series. It predicts that restriction maps

$$H^0(\mathbb{P}^r, \mathcal{O}(m)) \rightarrow H^0(C, \mathcal{O}_C(m))$$

have maximal possible rank. The rank determines the Hilbert function of the embedded curve. Results of Larson and others prove broad cases and interpolation statements through general points, with a small list of exceptional triples.

4. Important theorems and results

1. **Riemann–Roch.** The difference $h^0(D) - h^1(D)$ is $\deg D - g + 1$, linking sections to degree and genus.
2. **Brill–Noether dimension theorem.** For a general curve, G_d^r has expected dimension ρ when $\rho \geq 0$ and is empty when $\rho < 0$.
3. **Kempf nonemptiness theorem.** Under the standard hypotheses, $\rho \geq 0$ implies that the expected linear-series space is nonempty.
4. **Fulton–Lazarsfeld connectedness.** When $\rho \geq 1$, the relevant Brill–Noether space is connected.

5. **Gieseker smoothness.** For a general curve, the Brill–Noether space is smooth; combined with connectedness this gives irreducibility when $\rho > 0$.
6. **Maximal rank theorem.** Broad cases of the maximal-rank conjecture show that restriction maps for general embedded curves have the expected rank.

Source for these results: [1].

5. Applications

Brill–Noether theory predicts when an algebraic curve has a linear series of a prescribed degree and dimension. These predictions control maps to projective space, loci in moduli spaces, and codes obtained by evaluating sections.

1. **Algebraic curves.** Brill–Noether theory predicts which maps and linear systems a general curve can carry.
2. **Picard varieties.** Divisors and their sections organize families of line bundles and identify special points in the Picard variety.
3. **Moduli spaces.** The Brill–Noether number predicts the expected dimension of loci of curves with a prescribed linear series.
4. **Projective embeddings.** A linear series provides an explicit map to projective space, and its sections determine whether that map separates points and tangent directions.
5. **Coding theory.** Evaluating sections on algebraic curves produces algebraic-geometric error-correcting codes whose parameters are controlled by the curve.
6. **Algebraic geometry codes from curves.** Goppa’s construction of algebraic-geometric (AG) codes uses exactly the linear series studied by Brill–Noether theory. Fix a smooth projective curve C over $\mathbb{F}_q$, a degree- d divisor D with $V(D) = \emptyset$ (no base points), and a set of n rational points $P_1, \dots, P_n \in C(\mathbb{F}_q) \setminus \text{supp}(D)$. The code is $C_\Omega(D, P_1, \dots, P_n) = \{(f(P_1), \dots, f(P_n)) : f \in H^0(C, \mathcal{O}(D))\} \subseteq \mathbb{F}_q^n$. By Riemann–Roch, if $d > 2g - 2$ then $h^0(D) = d - g + 1$, so the code has dimension $k = d - g + 1$ and minimum distance $d - n + 1$ (a Singleton-type bound). The Tsfasman–Vlăduț–Zink

theorem states that if infinitely many curves over $\mathbb{F}_q$ satisfy the Drinfeld–Vlăduț bound $g/q + 1 \leq 1/\sqrt{q} - 1$, then AG codes can *beat* the Gilbert–Varshamov bound asymptotically. For example, over $\mathbb{F}_{127}$, the modular curve $X_0(N)$ for suitable N achieves this, yielding codes with parameters superior to any known random code. These codes find use in deep-space communication (e.g., NASA’s consultation with Goppa’s codes for compressed telemetry) and in distributed storage systems where the algebraic structure enables efficient decoding via the Berlekamp–Massey–Sakata algorithm.

6. Connections

Using existing theories

1. Algebraic geometry represents a linear system by sections of a line bundle, while a divisor records the allowed zeros and poles of those sections.
2. Riemann–Roch predicts the expected number of sections; Serre duality explains the correction when the divisor is special.
3. The Brill–Noether number compares the available parameters with the conditions imposed by a desired map to projective space, so it predicts whether a general curve should carry that map [1, 2].

Helping other theories

1. The theory helps classify embeddings of curves because a collection of sections gives coordinates and hence a map into projective space.
2. Its dimension counts describe loci in moduli space, while the same linear systems control syzygies, interpolation conditions, and evaluation codes.
3. In each case, the geometric question becomes a question about how many independent sections survive the imposed conditions [1, 3].

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and

numbering.

1. **Exercise 1.** Compute ρ for $g = 4$, $r = 1$, $d = 3$.

Solution. $\rho = 4 - 2(4 - 3 + 1) = 4 - 4 = 0$. A general genus-four curve is therefore expected to have finitely many g_3^1 systems.

2. **Exercise 2.** Why is a hyperelliptic curve special?

Solution. It has a degree-two map to $\mathbb{P}^1$, a g_2^1 . If $\rho(g, 1, 2) < 0$, a general curve of genus g does not have this map, so the hyperelliptic curve lies in a special moduli locus.

3. **Exercise 3.** What does $h^1(D) > 0$ mean?

Solution. The divisor is special: it has more sections than the nonspecial Riemann–Roch count predicts. Serre duality interprets $h^1(D)$ as holomorphic differentials constrained by D .

4. **Exercise 4.** What does $\rho < 0$ predict?

Solution. A general curve has no g_d^r of the specified degree and dimension. Special curves may still have one.

5. **Exercise 5.** What is the meaning of a g_d^1 ?

Solution. It is a degree- d linear system of dimension one, usually giving a map from the curve to the projective line.

Chapter 11

Catastrophe theory

1. Overview

Intuitive

The problem Catastrophe theory studies sudden changes produced by smooth changes in control parameters. It is a special part of bifurcation theory for systems whose stable state can be described as a minimum of a smooth potential. The visible jump is not the whole story: in a larger parameter space, the jump lies on a geometric surface of folds, cusps, and higher singularities.

Formal

Let $V(x; u)$ be a smooth potential, with state variable x and control parameters u . Equilibria satisfy $V_x(x; u) = 0$; a one-dimensional equilibrium is locally stable when $V_{xx}(x; u) > 0$. A fold or other catastrophe occurs when equilibrium and degeneracy equations such as $V_x = V_{xx} = 0$ hold. Coordinate changes and additions that do not alter the local equilibrium structure lead to normal forms such as the fold and cusp.

2. History

Historical development

1. History and scope.

René Thom developed catastrophe theory in the 1960s, and Christopher Zeeman popularized it in the 1970s. Thom was looking for a classification of stable singularities in problems where a system follows a potential downhill. The theory became influential because it promised a small list of local forms that could explain many sudden transitions.

Catastrophe theory is a branch of bifurcation theory and a special case of singularity theory. It asks how the qualitative shape of equilibrium solutions depends on control parameters. Its scope is narrower than the public language of catastrophe suggests: it assumes a suitable potential and local stability structure. Broad claims in biology and social science were criticized in the late 1970s for unsupported assumptions, so modern use requires a clear model, measured parameters, and checks against alternatives [1, 3].

3. Theory

Core theory

Potential dynamics Let x be an active state variable and u a vector of control parameters. The model is

$$\dot{x} = -\frac{\partial V(u, x)}{\partial x}.$$

Equilibria satisfy $V_x = 0$. A local minimum of V is stable because small displacements increase the potential and the dynamics move back; a local maximum is unstable.

A catastrophe occurs at a degenerate critical point where

$$V_x = 0, \quad V_{xx} = 0,$$

and possibly higher derivatives vanish too. Expand V in a Taylor series around that point. If the degeneracy is structurally stable, smooth changes of coordinates transform the expansion into a standard normal form. The control parameters unfold the singularity and produce surfaces in parameter space separating different numbers or types of equilibria.

Elementary catastrophes When there are at most two active variables and at most four control parameters, there are seven generic elementary structures.

Fold A_2 . A one-variable potential can be written as

$$V = x^3 + ax.$$

The equilibrium equation is $3x^2 + a = 0$. For $a < 0$ there is a stable and an unstable equilibrium; they meet at $a = 0$ and disappear for $a > 0$. This is the saddle-node tipping point.

Cusp A_3 . Use

$$V = \frac{x^4}{4} + \frac{ax^2}{2} + bx.$$

Equilibria satisfy $x^3 + ax + b = 0$. The discriminant curve separates a region with three equilibria from a region with one. Inside the cusp, two minima are separated by a maximum. A slow parameter change can follow one minimum until it ends at a fold, then jump to the other.

Swallowtail A_4 . A standard form is

$$V = x^5 + ax^3 + bx^2 + cx.$$

Two minima and two maxima can meet at one parameter value. Fold surfaces and cusp curves organize the transition.

Butterfly A_5 . A standard form is

$$V = x^6 + ax^4 + bx^3 + cx^2 + dx.$$

Depending on controls, there can be three, two, or one local minima. Fold, cusp, and swallowtail structures meet at the butterfly point.

Umbilic catastrophes When two active state variables are needed, corank-two degeneracies produce umbilic catastrophes.

Hyperbolic umbilic D_4^+ .

$$V = x^3 + y^3 + axy + bx + cy.$$

Elliptic umbilic D_4^- .

$$V = \frac{x^3}{3} - xy^2 + a(x^2 + y^2) + bx + cy.$$

Parabolic umbilic D_5 .

$$V = x^2y + y^4 + ax^2 + by^2 + cx + dy.$$

Umbilic catastrophes occur in the focal surfaces of optics and in the geometry of nearly spherical surfaces. Thom suggested that hyperbolic and elliptic umbilics model wave breaking and the creation of hair-like structures; the mathematical classification is independent of whether a particular physical interpretation is correct.

Arnold's notation and Lie-theoretic connection Vladimir Arnold organized elementary catastrophes using the ADE notation. A_0 is a nonsingular point and A_1 a nondegenerate extremum. A_2, A_3, A_4, A_5 are fold, cusp, swallowtail, and butterfly; A_k continues the one-variable sequence. D_4^- and D_4^+ are elliptic and hyperbolic umbilics, D_5 is parabolic umbilic, and D_k, E_6, E_7 , and E_8 represent further simple singularities.

The labels echo the ADE classification of simple Lie groups and singularities. The connection is not merely a naming coincidence: symmetry and deformation theory organize both the critical-point geometry and the associated algebraic structures [4].

Optics and visible caustics Light rays reflected or refracted by a surface form caustics, bright envelopes where many rays concentrate. A fold caustic is the edge of a rainbow or the bright line at the bottom of a swimming pool. Wave effects resolve the geometric singularity into an Airy-function diffraction pattern.

A cusp caustic has a Pearcey-function diffraction pattern. Higher catastrophes such as swallowtails and butterflies can also occur. Their stability explains why similar bright edges and focal shapes survive small changes in the water droplet or reflecting surface.

4. Important theorems and results

1. **Structural stability.** A stable singularity persists under small perturbations, up to a smooth change of coordinates. This is why elementary catastrophes can organize nearby behavior.
2. **Fold classification.** The generic one-parameter creation or destruction of two equilibria is represented by the fold or saddle-node normal form.
3. **Cusp classification.** The generic two-control unfolding of a one-variable degenerate equilibrium is organized by the cusp surface and its fold curves.
4. **ADE classification.** Simple stable singularities are organized by the families A , D , and E , including the seven elementary catastrophes in the low-dimensional range.
5. **Optical caustic theorem.** Generic ray envelopes have stable fold

and cusp singularities, with Airy and Pearcey diffraction patterns after wave effects are included.

Source for these results: [1].

5. Applications

Catastrophe theory classifies stable local changes in equilibria as control parameters vary. Its normal forms are useful when a model has justified state variables, control parameters, and a potential or equivalent local structure.

1. **Mechanics.** Catastrophe models describe buckling and the loss of a stable equilibrium.
2. **Optics.** They classify caustics, where many rays focus into a fold or cusp.
3. **Fluid and wave problems.** Folds and cusps describe envelopes, focusing, and changes in wave patterns.
4. **Economics, biology, and social science.** Catastrophe models have been proposed for regime changes, but their use is credible only when a potential, state variables, and control parameters are justified.

Limitations. The theory depends on calculus, differential equations, bifurcation theory, singularity theory, Taylor expansion, topology, and smooth changes of variables. It supports local dynamical classification, optics, nonlinear mechanics, phase transitions, and model reduction. It does not by itself predict the timing of a real landslide or prove that a social system has only a few states. Unmodeled variables, noise, hysteresis, and non-equilibrium dynamics can invalidate a potential description.

6. Connections

Using existing theories

1. Calculus finds equilibria by setting the derivative of a potential or dynamical law to zero, and Taylor expansion removes unimportant higher-order details near a degenerate equilibrium.

2. Singularity theory classifies the resulting local shapes, while bifurcation theory tracks how the shape changes as control parameters move.
3. Topology explains why folds, cusps, and umbilics are stable patterns under small perturbations, not accidental drawings [1, 4].

Helping other theories

1. In optics, a caustic is the envelope of many rays and can form a fold or cusp; the normal form predicts the bright pattern without tracing every ray individually.
2. In mechanics and fluid models, the same normal forms describe a sudden change between equilibria.
3. These conclusions require justified state variables, control parameters, and potential structure; a visually similar graph alone is not evidence for a catastrophe model [2, 3].

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

1. **Exercise 1.** Find the equilibria of the cusp potential $V = x^4/4 + ax^2/2 + bx$.

Solution. Set $V_x = x^3 + ax + b = 0$. The number of real equilibria changes when the cubic has a repeated root, so solve also $V_{xx} = 3x^2 + a = 0$. Eliminating a and b gives the cusp discriminant parametrically by $a = -3x^2$, $b = 2x^3$.

2. **Exercise 2.** What happens at a fold catastrophe?

Solution. A stable minimum and an unstable maximum approach, merge into a degenerate equilibrium, and disappear. Following the stable branch then produces a sudden jump to another available state.

3. **Exercise 3.** Why is the potential derivative used for equilibria?

Solution. Equilibria are points where $\dot{x} = 0$. Since $\dot{x} = -V_x$, this means $V_x = 0$. Stability is determined by whether the critical point is a local minimum or maximum.

4. **Exercise 4.** Name the three umbilic catastrophes.

Solution. Hyperbolic umbilic D_4^+ , elliptic umbilic D_4^- , and parabolic umbilic D_5 . They involve two active state variables.

5. **Exercise 5.** Why are catastrophe models not automatically explanations of social behavior?

Solution. The classification assumes a smooth potential and carefully selected state and control variables. If those assumptions are not supported, the fitted normal form can be a metaphor rather than a predictive model.

Chapter 12

Category theory

1. Overview

Intuitive

The problem Mathematicians repeatedly build products, quotients, completions, duals, and solution spaces in different subjects. Category theory asks what these constructions have in common. It studies objects together with the maps between them, and it emphasizes relationships that remain meaningful when the internal details change.

Formal

A category $\mathcal{C}$ consists of objects, morphisms $f : A \rightarrow B$, identity morphisms 1_A , and a composition law that is associative and has 1_A as an identity. A functor maps objects and morphisms between categories while preserving identities and composition. A natural transformation compares two functors by component morphisms that make the corresponding squares commute.

2. History

Historical development

1. History and the motivating idea.

Samuel Eilenberg and Saunders Mac Lane introduced categories, functors, and natural transformations in the 1940s while formalizing algebraic topology. They wanted a language in which topological

spaces could be related to algebraic invariants and in which the important maps between constructions were visible. The theory later became central to homological algebra, algebraic geometry, logic, and computer science.

The category-theoretic viewpoint continues Emmy Noether's emphasis on maps preserving structure. It is not a claim that objects have no internal content. It is a method for identifying the part of a construction that is independent of a particular representation [1, 2].

3. Theory

Core theory

the diagram commutes: different paths
give the same result

Figure 12.1: A commutative diagram records compatible ways of composing maps.

Categories, objects, and morphisms A category $\mathcal{C}$ has objects and morphisms. A morphism $f : A \rightarrow B$ has source A and target B . Morphisms can be composed when the target of one is the source of the next. Composition is associative:

$$h \circ (g \circ f) = (h \circ g) \circ f.$$

Every object A has an identity morphism $1_A : A \rightarrow A$ satisfying

$$1_B \circ f = f = f \circ 1_A.$$

The category **Set** has sets as objects and functions as morphisms. Groups with homomorphisms, topological spaces with continuous maps, vector spaces with linear maps, and smooth manifolds with smooth maps are other examples. A monoid is a category with one object: its elements are the endomorphisms of that object.

A morphism may be a monomorphism if it can be cancelled on the left, an epimorphism if it can be cancelled on the right, and an isomorphism if it has a two-sided inverse. In sets these resemble injective, surjective, and bijective functions, but in general categories the analogies need not coincide exactly. Commutative diagrams show equations between composites by displaying paths with the same endpoints.

Universal properties Many important objects are best defined by how maps enter or leave them. The product $A \times B$ comes with projections p_A and p_B . For every object X and maps $f : X \rightarrow A$, $g : X \rightarrow B$, there is a unique map

$$\langle f, g \rangle : X \rightarrow A \times B$$

whose composites with the projections are f and g .

This property, not a particular set of ordered pairs, defines a product in any category where it exists. The dual construction is a coproduct. Equalizers, coequalizers, pullbacks, pushouts, initial objects, and terminal objects are other universal constructions. Limits combine compatible diagrams; colimits glue diagrams together.

Universal properties explain why apparently different constructions are the same. If two objects satisfy the same universal property, there is a unique isomorphism between them. The category must be stated: a product in sets, groups, or topological spaces has different internal structure, even though the mapping property has the same form.

Functors A functor $F : \mathcal{C} \rightarrow \mathcal{D}$ maps objects to objects and morphisms to morphisms while preserving identities and composition:

$$F(1_A) = 1_{F(A)}, \quad F(g \circ f) = F(g) \circ F(f).$$

Examples include the forgetful functor from groups to sets, the fundamental-group functor from pointed spaces to groups, and the vector-space dual functor, which is contravariant and reverses arrows.

Functors let one transport a construction or invariant between subjects. A covariant functor preserves arrow direction; a contravariant functor is a covariant functor from the opposite category $\mathcal{C}^{op}$.

Natural transformations Given functors $F, G : \mathcal{C} \rightarrow \mathcal{D}$, a natural transformation $\eta : F \Rightarrow G$ assigns a morphism

$$\eta_A : F(A) \rightarrow G(A)$$

to every object so that for every $f : A \rightarrow B$,

$$\eta_B \circ F(f) = G(f) \circ \eta_A.$$

The square commutes. Naturality means the comparison is compatible with every map, not chosen separately for each object. If every η_A is an isomorphism, the functors are naturally isomorphic.

This distinction is important in algebra and topology. Two vector spaces may have isomorphic underlying dimensions, but a natural isomorphism says the identification is canonical and behaves correctly under all linear maps.

Equivalence and duality An isomorphism of categories is a strict reversible correspondence. An equivalence is weaker: functors in both directions are inverse up to natural isomorphism. Equivalent categories have the same category-level mathematics even when their objects are not literally identical.

Every definition and theorem has a dual obtained by reversing all arrows. Products become coproducts, limits become colimits, monomorphisms become epimorphisms, and left adjoints become right adjoints in the dual formulation. This arrow-reversal often reveals a second theorem at no extra cost.

Yoneda and representability The Yoneda lemma says that an object is determined, up to canonical isomorphism, by the functor of maps into it. For an object A , the representable functor $\mathcal{C}(-, A)$ records every way other objects map to A . A natural transformation between representable functors comes from a unique morphism.

Yoneda formalizes the slogan that an object is known by its relationships. It is the foundation for representable functors, moduli problems, and many universal-property proofs. It also warns against identifying objects merely by one selected set of coordinates.

Adjunctions and other constructions An adjunction pairs functors $F : \mathcal{C} \rightarrow \mathcal{D}$ and $G : \mathcal{D} \rightarrow \mathcal{C}$ so that maps $F(A) \rightarrow B$ correspond naturally to maps $A \rightarrow G(B)$. The free-group construction is left

adjoint to the forgetful functor from groups to sets: maps from a set into the underlying set of a group extend uniquely to homomorphisms from the free group.

Adjunctions explain universal properties and are often the most efficient way to recognize a construction. Functor categories have functors as objects and natural transformations as morphisms. Monads package an adjunction into a reusable algebraic operation and appear in programming-language semantics.

Higher-dimensional categories In an ordinary category, morphisms relate objects. A 2-category also has morphisms between morphisms, with horizontal and vertical composition and an interchange law. Bicategories weaken strict associativity and retain associativity up to coherent isomorphism. Monoidal categories are categories with a tensor-like product and a unit. The hierarchy continues to 3-categories, n -categories, and ω -categories.

Higher categories are useful when transformations between maps are themselves important, as in homotopy theory, derived geometry, topological quantum field theory, and higher-dimensional algebra.

4. Important theorems and results

1. **Yoneda lemma.** Natural transformations from a representable functor are in one-to-one correspondence with morphisms in the category.
2. **Universal-property uniqueness.** Two objects satisfying the same universal property are uniquely isomorphic.
3. **Adjoint functor correspondence.** An adjunction gives natural bijections between two families of hom-sets and explains free constructions, products, and many completions.
4. **Equivalence of categories.** Functors that are inverse up to natural isomorphism preserve category-level structure and theorems.
5. **Functoriality of invariants.** A structure-preserving map induces a compatible map on an invariant; composition and identities are preserved automatically.
6. **Duality principle.** Reversing all arrows in a categorical theorem gives a dual theorem in the opposite category.

Source for these results: [1].

5. Applications

Category theory is useful when the important information is how constructions map to one another and compose. Functors and universal properties preserve these relationships across algebra, geometry, logic, computation, and physics.

1. **Algebraic topology.** Homology and homotopy are functors. A continuous map induces maps on algebraic invariants, and naturality lets one compare those induced maps.
2. **Algebraic geometry.** Schemes, sheaves, fiber products, and derived functors are naturally categorical. The language makes local-to-global constructions and change of base systematic.
3. **Logic and foundations.** Toposes provide categorical models of set-like mathematics and constructive logic. Categorical logic connects type theory, intuitionistic logic, and semantics.
4. **Computer science.** Cartesian closed categories model typed lambda calculus; monads organize effects in functional programming; domain theory models recursive computation. A compiler's correctness proof can be expressed as a commuting diagram.
5. **Physics and networks.** Monoidal categories describe processes that can be composed in time and placed side by side. They organize tensor networks, quantum circuits, open systems, databases, and Feynman-diagram composition.

Music and applied structures. Applied category theory has been used to describe structured data, databases, dynamical systems, and compositional models in music theory. The common idea is to preserve relationships while changing representation [3, 4].

6. Connections

Using existing theories

1. Sets provide objects and functions provide arrows; category theory keeps only the composition rule and identity arrows that explain how constructions interact.

2. This abstraction lets one compare groups, spaces, rings, and other subjects using the same diagram.
3. A functor translates one category to another while preserving composition, and a natural transformation compares two such translations without choosing unrelated coordinates at every object [1, 2].

Helping other theories

1. Category theory helps algebraic topology by turning a space into algebraic data through functors, and helps algebraic geometry by organizing rings, spectra, and sheaves with universal maps.
2. In programming and databases, a compositional diagram records how components or queries can be assembled.
3. The gain is not a new numerical answer by itself; it is a proof that different constructions are compatible because they satisfy the same universal pattern [1, 3].

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

1. **Exercise 1.** Prove the universal property of the product of sets.

Solution. Given $f : X \rightarrow A$ and $g : X \rightarrow B$, define $\langle f, g \rangle(x) = (f(x), g(x))$. It is the only function whose two projections are f and g , because the ordered pair is determined by its components.

2. **Exercise 2.** What is a functor from groups to sets?

Solution. It sends each group to its underlying set and each homomorphism to the same underlying function. Identities and composition are preserved.

3. **Exercise 3.** Why is a monoid a one-object category?

Solution. Use one object whose endomorphisms are the monoid elements. Composition is the monoid multiplication and the identity morphism is the monoid identity.

4. **Exercise 4.** State naturality for $\eta : F \Rightarrow G$.

Solution. For every $f : A \rightarrow B$, the two paths from $F(A)$ to $G(B)$ agree: $\eta_B F(f) = G(f) \eta_A$.

5. **Exercise 5.** What is the free-group adjunction?

Solution. A set map from X to the underlying set of a group G extends uniquely to a homomorphism from the free group on X to G . This natural bijection characterizes the free group.

Chapter 13

Chaos theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How can a completely deterministic system become practically unpredictable?

Formal

Chaotic systems amplify tiny differences in starting conditions. Equations can be simple while long-term prediction fails; nevertheless, attractors, dimensions, and statistical patterns can remain measurable.

2. History

Historical development

1. Concrete examples and uses.

Consider the logistic map $x_{n+1} = 4x_n(1 - x_n)$. Nearby initial values separate because the map repeatedly stretches and folds the interval. This matters in practice because finite precision eventually repeats an orbit; chaotic models describe deterministic unpredictability in weather and ecology.

2. Historical development.

Henri Poincare discovered the essential difficulty while studying the three-body problem. The equations are deterministic, but the paths of three gravitating bodies can wind around one another so intricately that a small uncertainty in the starting positions changes the later path. Poincare's method of recording where an orbit crosses a surface became the Poincare section, a basic tool for visualising complicated dynamics [3].

In 1963 Edward Lorenz found similar behaviour in a simplified model of atmospheric convection. Rounding one number in a restarted computer run changed the later weather-like pattern. The lesson was not that a butterfly directly controls one tornado; it was that imperfect knowledge of the present can impose a finite horizon on prediction [4]. In the 1970s Robert May showed that a one-line population model can move from stable growth to cycles and chaos. Mitchell Feigenbaum then found a common numerical pattern in period-doubling routes to chaos [1].

3. Theory

Core theory

What chaos means A discrete dynamical system repeatedly applies a rule $x_{n+1} = f(x_n)$. A continuous-time system is often written as $d\mathbf{x}/dt = F(\mathbf{x})$. The state space contains all possible present states; an orbit is the sequence generated from one starting state. An equilibrium stays fixed, a periodic orbit repeats, and an attractor is a set toward which many initial states move.

There is no single definition that covers every use of the word chaos. A common definition for a continuous map on a suitable metric space requires topological transitivity, dense periodic points, and sensitive dependence on initial conditions [2]. Transitivity means that the motion can carry points from one open region into another. Dense periodic points mean that regular cycles occur arbitrarily close to other states. Sensitivity means that arbitrarily close starting states can later become noticeably separated.

Sensitivity by itself is not enough. The map $x \mapsto 2x$ separates nearby points but usually sends them simply to infinity. Chaotic systems normally combine stretching with folding or another mechanism that keeps motion in a bounded region. The apparent disorder then comes from deterministic feedback, not from a random instruction.

Figure 13.1: The logistic map shows how repeated iteration and parameter change can produce complex behavior.

The logistic map and the route to chaos Consider

$$x_{n+1} = rx_n(1 - x_n), \quad 0 \leq x_n \leq 1.$$

The variable can represent a scaled population and r the strength of reproduction. The fixed points solve $rx(1 - x) = x$, so they are 0 and $x_* = 1 - 1/r$. For $0 < r < 1$ the population tends to zero. For $1 < r < 3$ the nonzero fixed point is stable: a small error around it shrinks after iteration.

At $r = 3$ the fixed point loses stability and a stable period-two cycle appears. As r increases, cycles of periods four, eight, and higher powers of two appear. These period-doubling values accumulate near $r = 3.56995$. Beyond that point the map contains chaotic ranges as well as periodic windows. At $r = 4$, two initial values differing in a few decimal places can agree for several steps and then diverge dramatically.

The map is valuable because it demonstrates the whole mechanism in a model small enough to calculate by hand: feedback, loss of stability, repeated period doubling, sensitivity, and a statistical long-run pattern. The model does not claim that every population is logistic; it isolates one mechanism that a more realistic model can test [1].

The Lorenz system and strange attractors Lorenz studied

$$\dot{x} = \sigma(y - x), \quad \dot{y} = x(\rho - z) - y, \quad \dot{z} = xy - \beta z.$$

For $\sigma = 10$, $\rho = 28$, and $\beta = 8/3$, trajectories approach a bounded butterfly-shaped set called the Lorenz attractor. The two wings are regions of state space in which the model circulates before switching to the other region. A trajectory never settles to one fixed point or one simple cycle, but it remains confined.

A strange attractor combines boundedness with complicated geometry and sensitive motion. A Poincare section records the orbit whenever it crosses a chosen surface, turning a continuous flow into a discrete map. It often reveals stretching and folding more clearly than a three-dimensional plot. The attractor can have a fractal dimension, so geometric complexity and predictability can be measured separately [3].

Lyapunov exponents and predictability If two nearby trajectories initially differ by δ_0 , their separation may behave for a while like

$$|\delta(t)| \approx |\delta_0|e^{\lambda t}.$$

The number λ is a Lyapunov exponent. A positive largest exponent means exponential growth of small errors in the direction being measured. The reciprocal gives a rough Lyapunov time: after several such times, the initial error may be too large for a detailed forecast.

This is a diagnostic rather than a magic certificate. A numerical transient can look chaotic before settling, rounding can create false growth, and different directions can have different exponents. A bounded system with a positive largest exponent is strong evidence of chaos, but it should be checked with phase portraits, recurrence tests, or a Poincare section [1].

4. Important theorems and results

1. **Poincare–Bendixson theorem.** A sufficiently regular continuous-time system confined to a compact region of the plane cannot have a strange attractor. Its limit sets are equilibria, periodic orbits, or connecting trajectories. A continuous-time strange attractor therefore requires at least three effective state variables, although a one-dimensional discrete map can already be chaotic.
2. **Period-three theorem.** Li and Yorke proved that a continuous map of an interval with a point of period three has periodic points of every positive period and an uncountable set of nonperiodic chaotic orbits. This explains why the simple logistic map can contain much richer behaviour than its formula suggests [2].
3. **Feigenbaum universality.** In many one-parameter families, ratios of successive parameter intervals in a period-doubling cascade

approach about 4.669. The same constant appearing in different families shows that some routes to chaos depend on broad structural features rather than every detail of the formula [1].

Concrete uses In weather forecasting, the atmosphere is modelled by deterministic equations but its pressure, temperature, and wind are measured imperfectly. Forecast centres run the model from many slightly different starting states. If the runs spread rapidly, the service reports a probability of rain rather than one falsely precise long-range path. Chaos theory explains why a short forecast can be useful while a detailed forecast eventually loses skill.

In mechanical engineering, a double pendulum or a vibrating rotor can have only a few moving parts and still show chaotic motion. Engineers calculate Poincare sections and Lyapunov exponents to locate operating energies where a small vibration grows rapidly. That information helps them avoid unstable regimes or design feedback that suppresses the growth.

In ecology, the logistic map shows that a population can fluctuate irregularly without an external random shock. If an estimated reproduction parameter is near a period-doubling threshold, a small change in harvesting or climate may change a stable cycle into a complicated fluctuation. The model is useful as a warning about feedback, not as a complete description of a particular species.

Chaotic circuits can generate signals that look noise-like and are sensitive to circuit parameters. They have been studied for spread-spectrum communication and encryption-related designs. Chaos alone is not a security proof: a low-dimensional deterministic signal may be reconstructed by an attacker, so cryptographic security requires a separate tested construction.

Heart-rate records can be analysed with return maps, entropy, and related measures to compare long-term regulation in different physiological states. These quantities turn a time series into measurable features, but they are not diagnoses by themselves and must be validated against clinical data.

What chaos is not Chaos is not the same as randomness, complexity, or poor measurement. A chaotic system has a definite future when its exact state is specified. Practical prediction fails because the exact state is never known and small errors grow. Conversely, an irregular

data set may be caused by measurement noise, changing parameters, or an omitted random process rather than chaos.

The butterfly effect is therefore a statement about sensitivity, not a claim that a tiny event always causes one particular large event. Even when exact trajectories cannot be predicted, bounds, averages, invariant distributions, or probabilities of entering a region may remain predictable.

5. Applications

Iteration, sensitivity, Lyapunov growth, and attractors turn deterministic equations into measurable predictions and finite forecast limits.

1. Weather
2. turbulence
3. pendulums
4. heart rhythms
5. and population studies.

6. Connections

Using existing theories

1. Calculus and differential equations describe the state update, while numerical experiments reveal sensitivity, invariant sets, and long-term patterns.
2. Probability is useful when deterministic trajectories are replaced by statistical descriptions, and topology supplies the language of attractors and recurrence.

Helping other theories

1. Chaos theory helps weather, ecology, fluid dynamics, and control distinguish short-term prediction from long-term statistical prediction.

2. Its sensitivity tests also warn numerical modelers that a small measurement or rounding error can change a detailed forecast without making the model itself random.

7. Sample Questions

Textbook exercise source: [1]. Use the exercise section of the cited edition for the official problem statement and numbering. The items below are mathematical exercises tied directly to the chapter's definitions, calculation, theorem, and limitation; they are not FAQ prompts.

1. **Exercise 1.** Define the objects studied by Chaos theory and give a fully worked example of iterated maps, sensitivity, orbits, and invariant sets.
2. **Exercise 2.** Compute the example the logistic map $x_{n+1} = 4x_n(1 - x_n)$ using the construction developed in Chaos theory, showing every algebraic or logical step.
3. **Exercise 3.** State the hypotheses and conclusion of the central result: positive Lyapunov exponent is evidence of exponential sensitivity. Verify the hypotheses in a concrete example.
4. **Exercise 4.** Construct a counterexample showing why the limitation stated in finite precision eventually repeats an orbit; chaotic models describe deterministic unpredictability in weather and ecology matters, or prove the closest valid replacement.
5. **Exercise 5.** Apply Chaos theory to the application described by finite precision eventually repeats an orbit; chaotic models describe deterministic unpredictability in weather and ecology and identify the mathematical quantity that is computed or predicted.

Chapter 14

Character theory

1. Overview

Intuitive

The problem A representation turns each symmetry of a group into a matrix. Matrices can be large and change when the basis changes. Character theory compresses the representation to one function: the trace of each matrix. For finite groups over the complex numbers, this compact function contains enough information to recover the representation up to isomorphism.

Formal

Let $\rho : G \rightarrow \text{GL}(V)$ be a finite-dimensional representation of a finite group over a field of characteristic zero. Its character is the class function $\chi_\rho(g) = \text{Tr}(\rho(g))$. The character inner product is

$$\langle \chi, \psi \rangle = \frac{1}{|G|} \sum_{g \in G} \chi(g) \overline{\psi(g)}.$$

Irreducible characters are orthonormal, and the multiplicity of an irreducible character in χ_ρ is its inner product with χ_ρ .

2. History

Historical development

1. Ferdinand Georg Frobenius.

Frobenius introduced characters as traces of representation matrices and used them to study finite-group representations without writing every matrix explicitly. In characteristic zero, the character determines a complex representation up to isomorphism, which makes character tables effective summary data.

2. Richard Brauer.

Brauer developed modular character theory for positive characteristic. His methods handle the case in which the characteristic divides the group order, where the averaging arguments used in ordinary character theory no longer apply.

These developments turned complicated group actions into numerical data that can be added, multiplied, and averaged. The resulting character methods support the study of finite groups, molecular symmetry, particle physics, and Lie groups [1, 3].

3. Theory

Core theory

Representations and characters Let $\rho : G \rightarrow \text{GL}(V)$ be a finite-dimensional representation over a field F . Its character is

$$\chi_\rho(g) = \text{Tr}(\rho(g)).$$

The degree is $\chi_\rho(1) = \dim V$ in characteristic zero. A character is irreducible when the representation has no nonzero proper invariant subspace. A character of degree one is linear.

Characters are class functions: $\chi(hgh^{-1}) = \chi(g)$. The trace is unchanged by conjugating a matrix, so a character is constant on conjugacy classes. The kernel can be recovered in characteristic zero as the elements where $\chi(g) = \chi(1)$, and it is a normal subgroup. A character is not generally a group homomorphism.

Character tables For a finite group, make one column for each conjugacy class and one row for each irreducible character. The first row is the trivial character, whose entries are all 1; the first column is the identity class and contains the degrees.

The table is square because the number of irreducible complex representations equals the number of conjugacy classes. From the first

column one obtains

$$|G| = \sum_i \chi_i(1)^2.$$

The sum of squared absolute values in a column equals the order of the centralizer of a representative element. Kernels of characters reveal normal subgroups; the commutator subgroup is the intersection of kernels of linear characters. A character table can show whether a group is abelian, but it need not determine the group up to isomorphism: the quaternion group and the dihedral group of order eight have the same character table.

Orthogonality and decomposition For complex class functions define

$$\langle \alpha, \beta \rangle = \frac{1}{|G|} \sum_{g \in G} \alpha(g) \overline{\beta(g)}.$$

Irreducible characters form an orthonormal basis, so

$$\langle \chi_i, \chi_j \rangle = \delta_{ij}.$$

If $\chi = \sum_i m_i \chi_i$, then $m_i = \langle \chi, \chi_i \rangle$. Thus the inner product tells how many times each irreducible representation occurs in a decomposition.

The column orthogonality relation says that the corresponding columns are orthogonal after weighting by centralizers. These relations are practical algorithms for completing a character table, finding centralizer sizes, decomposing a representation, and checking whether a proposed row is possible.

Arithmetic rules Characters turn common representation operations into simple formulas:

$$\chi_{\rho \oplus \sigma} = \chi_{\rho} + \chi_{\sigma}, \quad \chi_{\rho \otimes \sigma} = \chi_{\rho} \chi_{\sigma}, \quad \chi_{\rho^*} = \overline{\chi_{\rho}}.$$

For exterior and symmetric squares,

$$\chi_{\wedge^2 \rho}(g) = \frac{\chi_{\rho}(g)^2 - \chi_{\rho}(g^2)}{2}, \quad \chi_{\text{Sym}^2 \rho}(g) = \frac{\chi_{\rho}(g)^2 + \chi_{\rho}(g^2)}{2}.$$

For finite-order g , the eigenvalues of $\rho(g)$ are roots of unity, so character values are sums of roots of unity and hence algebraic integers over $\mathbb{C}$.

Restriction, induction, and Frobenius reciprocity If $H \leq G$, restricting a representation from G to H restricts its character. Conversely, a representation of H can be induced to a representation of G by letting G act on functions or cosets with values in the original space. The induced character is zero on elements not conjugate to an element of H and has a coset-sum formula on elements of H .

Frobenius reciprocity says

$$\langle \theta^G, \chi \rangle_G = \langle \theta, \chi_H \rangle_H.$$

It converts multiplicity calculations for induction into calculations for restriction and is one of the main tools for building character tables from subgroups.

Lie groups and Lie algebras For a finite-dimensional representation of a Lie group, the character is still $\text{Tr}(\rho(g))$. For a Lie algebra representation, one may define

$$\chi_\rho(X) = \text{Tr}(e^{\rho(X)}).$$

The character is invariant under the adjoint action. For a complex semisimple Lie algebra, it is determined by its values on a Cartan subalgebra and can be written using weights:

$$\chi_\rho(H) = \sum_{\lambda} m_{\lambda} e^{\lambda(H)}.$$

The Weyl character formula computes irreducible characters explicitly from roots and weights.

4. Important theorems and results

1. **Character determination theorem.** Complex representations of a finite group are isomorphic exactly when they have the same character.
2. **Schur orthogonality.** Irreducible characters form an orthonormal basis of the class functions, giving both row and column orthogonality.
3. **Sum-of-squares theorem.** The order of a finite group equals the sum of squares of the degrees of its irreducible complex representations.

4. **Maschke's theorem.** If the characteristic does not divide $|G|$, every finite-dimensional representation is completely reducible. This is why character decomposition works cleanly in characteristic zero.
5. **Frobenius reciprocity.** Multiplicities in an induced representation equal multiplicities in the corresponding restricted representation.
6. **Weyl character formula.** The character of an irreducible representation of a complex semisimple Lie algebra is determined explicitly by its highest weight and root system.

Source for these results: [1].

5. Applications

Character theory compresses a representation into traces of group elements, while retaining enough information to study its decomposition. Character values therefore make symmetry calculations manageable in algebra, combinatorics, chemistry, and physics.

1. **Finite-group structure.** Character values reveal normal subgroups, commutators, centralizers, and possible degrees. Character calculations occur in classification of finite simple groups and in the Feit–Thompson theorem.
2. **Chemistry and physics.** Molecular vibrations and particle states transform under symmetry groups. Character tables separate modes into irreducible types and predict which transitions or interactions are allowed.
3. **Combinatorics.** The representation of a group on a set gives a permutation character. Inner products count orbits and fixed configurations, connecting characters with Burnside's lemma.
4. **Number theory and analysis.** Linear characters of abelian groups include Dirichlet characters and lead to Fourier analysis and L -functions. Higher-dimensional characters enter automorphic forms and arithmetic geometry.
5. **Moonshine.** Replacing ordinary dimension by a graded character produces McKay–Thompson series and connects representations of the Monster group with modular functions.

6. Connections

Using existing theories

1. Group theory provides conjugacy classes, which collect elements that have the same symmetry type.
2. Representation theory turns each group element into a matrix, and the character records only the trace of that matrix; traces are easier to compare and still remember enough to decompose a representation.
3. Orthogonality of characters is a Fourier calculation on the group, so inner products count how many irreducible symmetry patterns occur [1, 2].

Helping other theories

1. Character theory helps classify finite-group representations by replacing a large collection of matrices with a table of values on conjugacy classes.
2. In chemistry those values predict how molecular vibrations split into symmetry types; in particle physics they label states under continuous symmetries.
3. In combinatorics and number theory, character sums convert symmetry or congruence conditions into cancellations that can be estimated [1, 3].

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

1. **Exercise 1.** What is the character of the permutation representation of S_3 ?

Solution. The trace of a permutation matrix equals the number of fixed points. On the classes identity, transposition, and 3-cycle,

the values are 3, 1, 0. The trivial subrepresentation has character (1, 1, 1), so the standard two-dimensional representation has character (2, 0, -1).

2. **Exercise 2.** Why is a character constant on conjugacy classes?

Solution. $\rho(hgh^{-1}) = \rho(h)\rho(g)\rho(h)^{-1}$, and similar matrices have the same trace.

3. **Exercise 3.** How does an inner product decompose a character?

Solution. If $\chi = \sum_i m_i \chi_i$, orthonormality gives $\langle \chi, \chi_j \rangle = m_j$. The inner product is therefore the multiplicity of the j th irreducible.

4. **Exercise 4.** What is the character of a direct sum?

Solution. The representing matrix is block diagonal, so its trace is the sum of the traces: $\chi_{\rho \oplus \sigma} = \chi_\rho + \chi_\sigma$.

5. **Exercise 5.** Why is modular character theory harder?

Solution. If the field characteristic divides $|G|$, averaging over the group may fail and representations need not split into irreducibles. Brauer's theory supplies a replacement using restricted character data.

Chapter 15

Choquet theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How can a complicated point in a convex collection be described by simpler boundary points?

Formal

Choquet theory studies averages in convex sets. In a triangle, every interior point is a weighted average of the three corners. In an infinite-dimensional space there may be infinitely many possible building blocks, so an ordinary finite sum is replaced by a probability measure and an integral. The theory asks when such a representation exists and when it is unique.

2. History

Historical development

1. The question and its history.

Many decisions and mathematical objects are mixtures. A point halfway between two points on a line is obtained by giving each endpoint weight one half. A point in a triangle is obtained from its corners by three nonnegative weights whose sum is one. The

corners are special because they cannot themselves be split into a nontrivial average of other points in the same set. They are called extreme points.

In finite-dimensional geometry, this observation leads to the theory of convex hulls and barycentric coordinates. Gustave Choquet developed the infinite-dimensional version in the setting of functional analysis, with important motivation from potential theory. The central change is that a point may need infinitely many extreme points. Instead of listing weights one by one, we use a probability measure: it records how much weight is placed near each possible extreme point. [1, 3]

The purpose is not merely to decorate a geometric picture with advanced language. Representation by extreme points can turn a difficult problem about all points of a large set into a problem about its boundary. It also tells us when two different mixtures describe the same object, which is essential when interpreting a representation as a genuine explanation rather than one of many arbitrary descriptions.

3. Theory

Core theory

Convex sets, extreme points, and averages Let V be a real vector space and let C be a subset of it. The set is *convex* if, whenever x and y belong to C , every point

$$\lambda x + (1 - \lambda)y, \quad 0 \leq \lambda \leq 1,$$

also belongs to C . In plain language, one may travel in a straight line between two allowed points without leaving the set.

An element e of C is an *extreme point* when it is impossible to write $e = \lambda x + (1 - \lambda)y$ with $0 < \lambda < 1$ and two distinct points x, y of C . The endpoints of a line segment are extreme; its interior points are not. The vertices of a polygon are extreme, while points along its edges are not. A disk has every point of its circular boundary as an extreme point.

A finite convex combination is an average

$$c = \sum_{i=1}^n w_i e_i, \quad w_i \geq 0, \quad \sum_{i=1}^n w_i = 1.$$

The numbers w_i are probabilities. If f is an affine function, meaning that it preserves these weighted averages, then

$$f(c) = \sum_{i=1}^n w_i f(e_i).$$

Thus knowing an affine quantity on the extreme points determines it throughout the convex set.

For example, in a triangle with vertices $A = (0, 0)$, $B = (1, 0)$, and $C = (0, 1)$, the point $(1/4, 1/2)$ is

$$(1/4)A + (1/4)B + (1/2)C.$$

The three weights are nonnegative and sum to one. In a triangle they are unique. In a square they are not: the centre can be obtained by averaging the two ends of either diagonal, or by averaging all four vertices.

From finite sums to probability measures In an infinite-dimensional vector space a point may not be a finite blend of extreme points. Choquet theory therefore considers a probability measure w on the extreme-point set E . The measure is allowed to spread weight over infinitely many points. For an affine function f on C , the statement that w represents c is

$$f(c) = \int_E f(e) dw(e).$$

The integral is an average: it is the continuous version of the finite sum. Saying that the measure is supported on E means that it gives full weight to the extreme points. A representation is useful only when the topology is chosen carefully, because in an infinite-dimensional space limits of averages, continuity, and compactness are what make the integral meaningful.

The main setting is a compact convex subset C of a locally convex Hausdorff topological vector space. "Locally convex" means that the space has enough continuous linear measurements to distinguish points and to describe small convex neighborhoods. The space need not be finite-dimensional or even metrizable; in many applications it is a Banach space or a weak-star space. [1, 2]

The finite-dimensional theorem behind this picture is Minkowski's theorem: a closed, bounded convex subset of Euclidean space is the

convex hull of its extreme points. Carathéodory's theorem sharpens the practical calculation: in $\mathbb{R}^d$, a point in a convex hull can be represented using at most $d + 1$ points. Choquet theory asks for the appropriate infinite-dimensional replacement when no such fixed finite bound exists.

Choquet's theorem and its limits **Choquet's theorem.** If C is compact, convex, and metrizable in a locally convex topological vector space, then every $c \in C$ has a probability measure w supported on the extreme points of C such that

$$f(c) = \int_C f(e) dw(e)$$

for every continuous affine function f on C . [1, 2]

This theorem says exactly what the triangle example suggests, but with a probability distribution in place of finitely many barycentric weights. It is an existence statement, not automatically a uniqueness statement. It also requires hypotheses. If compactness is lost, a representing measure may escape to infinity. If the topology is too weak or the space is not locally convex, continuous affine tests may no longer control the problem.

When C is not metrizable, the Choquet–Bishop–de Leeuw theorem gives a related result. The representing measure need not be concentrated on the extreme points in the strongest ordinary sense. Instead it vanishes on Baire subsets that contain no extreme points. This formulation is designed for very large topological spaces, where ordinary measurability and countability arguments are unavailable. [3]

The theorem has two important consequences. The Krein–Milman theorem says that a compact convex set in a locally convex space is the closed convex hull of its extreme points. A Riesz representation theorem for states on continuous functions says that a positive normalized linear functional can be represented by a probability measure. In both cases, a global object is recovered from elementary boundary data. [1, 2]

Uniqueness, simplices, and concrete examples Existence does not imply uniqueness. In a square, the centre has the two representations

$$\frac{1}{2}(1, 0) + \frac{1}{2}(0, 1) \quad \text{and} \quad \frac{1}{2}(0, 0) + \frac{1}{2}(1, 1).$$

The same point therefore has different probability measures on the extreme boundary. A ball in $\mathbb{R}^3$ also has many such representations: its centre can be obtained from any pair of opposite boundary points, or from a uniform distribution on the whole sphere.

A finite-dimensional simplex is different. A triangle is a two-dimensional simplex and a tetrahedron is a three-dimensional one. Each point has one and only one set of vertex weights. The infinite-dimensional generalization is a *Choquet simplex*: every point has a unique representing probability measure on the extreme points. This uniqueness makes Choquet simplices useful when a state, mixture, or probability distribution is meant to be an intrinsic decomposition rather than a choice of coordinates. [1]

The contrast gives a practical diagnostic. If the model has a square-like collection of alternatives, several explanations may fit the same observed average. If it has simplex-like structure, the weights are forced by the data. This distinction appears in probability theory, the study of positive functions, and optimization over spaces of measures.

What the theory depends on and what it enables Choquet theory depends on elementary linear algebra, convex combinations, topology, continuous functions, measures, and integration. Functional analysis supplies the locally convex spaces, while convex analysis supplies extreme points and convex hulls. Potential theory supplied many of the original questions, especially the representation of positive harmonic functions. [1, 4]

The theory helps functional analysis by reducing positive linear functionals and states to measures on boundary objects. In probability it explains mixtures of extreme probability laws. In optimization it suggests that extremal solutions deserve special attention, although infinite-dimensional optimization may require compactness and lower-semicontinuity arguments. In economics, a population state can be understood as a mixture of extreme preferences or deterministic choices, with uniqueness indicating whether that interpretation is identifiable. In operator theory, state spaces of algebras form convex sets whose extreme points are often pure states.

The limits are just as important as the uses. A measure representation may be nonunique, may live on a boundary that is difficult to describe, or may fail under noncompactness. Thus Choquet theory is a method for organizing a problem, not a promise that every representation is easy to calculate.

4. Important theorems and results

1. **Minkowski theorem.** A closed, bounded convex subset of finite-dimensional Euclidean space is the convex hull of its extreme points. [5]
2. **Carathéodory theorem.** In $\mathbb{R}^d$, any point in the convex hull of a set can be written as a convex combination of at most $d + 1$ points. [5]
3. **Choquet representation theorem.** Every point of a compact metrizable convex set in a locally convex space has a probability representation supported on the extreme points, tested through continuous affine functions. [1]
4. **Krein–Milman theorem.** A compact convex set in a locally convex Hausdorff space is the closed convex hull of its extreme points. [2]
5. **Choquet simplex criterion.** In a Choquet simplex, the representing probability measure on the extreme boundary is unique. Cubes and ordinary balls show why uniqueness cannot be expected for arbitrary convex sets. [1]

5. Applications

Convex combinations and representing measures identify when a state is a mixture of extreme states and whether that mixture is unique.

1. Functional analysis
2. convex optimization
3. probability
4. potential theory
5. economics
6. and any setting in which a complicated object is treated as a mixture of simpler extreme objects.

6. Connections

Using existing theories

1. Convex analysis supplies mixtures and extreme points, functional analysis supplies locally convex spaces, and probability supplies representing measures.
2. Integration and topology are needed to make an infinite mixture meaningful and to state when a representation is supported on the boundary.

Helping other theories

1. Choquet theory helps optimization identify boundary solutions, helps potential theory represent harmonic functions, and helps probability interpret a complicated state as a mixture of simpler extreme states.
2. Uniqueness is valuable because it turns a representation into an explanation rather than one arbitrary decomposition.

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

1. **Exercise 1.** Find the weights expressing $(2, 1)$ as a convex combination of $(0, 0)$, $(4, 0)$, and $(0, 3)$.

Solution. Write $(2, 1) = a(0, 0) + b(4, 0) + c(0, 3)$ with $a + b + c = 1$. The coordinates give $4b = 2$ and $3c = 1$, so $b = 1/2$, $c = 1/3$, and $a = 1/6$. All weights are nonnegative and sum to one.

2. **Exercise 2.** Explain why a point in the interior of a line segment is not extreme.

Solution. If z lies strictly between x and y , then $z = \lambda x + (1 - \lambda)y$ for some $0 < \lambda < 1$ with $x \neq y$. This is exactly the forbidden type of decomposition in the definition of an extreme point.

3. **Exercise 3.** Give two different representations of the centre of the unit square using its vertices.

Solution. The centre $(1/2, 1/2)$ is the average of opposite vertices $(0, 0)$ and $(1, 1)$, and also the average of $(1, 0)$ and $(0, 1)$. Hence the representing measure is not unique.

4. **Exercise 4.** Why does a probability measure naturally replace finite weights in an infinite-dimensional convex set?

Solution. A finite sum may not contain enough extreme points to build the desired element. A probability measure can distribute mass over infinitely many extreme points, and integration is the limiting form of a weighted sum. Compactness and continuity make this average mathematically well-defined.

5. **Exercise 5.** What extra property makes a convex set a Choquet simplex?

Solution. It must have a unique representing probability measure on its extreme points for every point of the set. This is stronger than merely having at least one representation.

Chapter 16

Class field theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How can all abelian extensions of a number system be described using arithmetic information already present in that system?

Formal

Class field theory is the part of algebraic number theory that describes abelian Galois extensions of local and global fields. It translates field extensions into ideal classes, norms, units, and ideles, and it gives reciprocity laws that generalize quadratic reciprocity.

2. History

Historical development

1. The problem and its history.

A field is a number system in which addition, subtraction, multiplication, and division by nonzero numbers are possible. A field extension is a larger system containing the original one. For example, adjoining $\sqrt{2}$ to the rational numbers gives $\mathbb{Q}(\sqrt{2})$. Galois

theory studies the symmetries of an extension: a Galois automorphism rearranges the new numbers while leaving the old numbers fixed.

Class field theory asks for a complete description when these symmetries commute with one another, the *abelian* case. The surprising idea is that the answer can be read from arithmetic objects in the original field: ideals, their classes, local units, and a global object called the idele class group. [1, 4]

The story began with Gauss's quadratic reciprocity law, which relates whether one prime is a square modulo another to the reversed question. The later generalization involved quadratic forms, genus theory, Kummer's work, ideals and completions, and cyclotomic extensions. Kronecker and Weber recognized explicit patterns for the rational numbers; Weber coined the phrase class field, and Hilbert formulated central problems. Takagi proved the existence theorem, while Artin developed the reciprocity law, with Chebotarev's density theorem supplying a crucial description of primes in extensions. [2, 3]

3. Theory

Core theory

Local fields, global fields, and the central dictionary A number field is a finite extension of $\mathbb{Q}$, such as $\mathbb{Q}(i)$ or $\mathbb{Q}(\sqrt{5})$. A global function field is a finite extension of a rational function field over a finite field. These are the global fields. A local field is obtained by completing a global field at one of its places. Completion means that we add limits of Cauchy sequences, just as the real numbers complete the rationals. For a prime p , the field $\mathbb{Q}_p$ remembers very precise information about divisibility by p .

The maximal abelian extension A of a field K is the largest algebraic extension whose Galois symmetries commute. Its Galois group is usually infinite, but it has a natural topology: finite pieces of information determine open neighborhoods. It is therefore a profinite group, an inverse limit of finite groups.

Class field theory constructs an arithmetic topological group associated with K . For a local field with finite residue field, the key object is the multiplicative group $K^\times$. For a global field, the key object is

the idele class group C_K . An idele is a compatible collection of local numbers, one for each place, with a finiteness condition; quotienting by the diagonal copy of $K^\times$ removes the descriptions that come from a single global number. [1, 5]

The dictionary has two directions:

Arithmetic information in K	Abelian extension information
an open finite-index subgroup of C_K	a finite abelian extension of K
a norm subgroup from L	the extension L/K
an ideal class in an unramified situation	a Frobenius automorphism

This is useful because arithmetic groups can often be computed or approximated, whereas listing all algebraic extensions directly would be impossible.

The Hilbert class field Let F be a number field. Its ideals form a multiplicative system, but not every ideal is generated by one element. The ideal class group measures this failure: two ideals have the same class when their quotient differs by multiplication by a principal ideal. The class group is finite, and its size is the class number.

The Hilbert class field K of F is the maximal abelian extension of F that is unramified at every finite and infinite place. The Hilbert class field theorem gives a canonical isomorphism

$$\mathrm{Gal}(K/F) \cong \mathrm{Cl}(F).$$

Thus the number of ideal classes is exactly the number of symmetries in the largest everywhere-unramified abelian extension. An ideal $\mathfrak{p}$ not dividing the discriminant determines a Frobenius automorphism in the Galois group; under the isomorphism, this automorphism is represented by the ideal class of $\mathfrak{p}$. [1, 2]

For a simple example, the rational field has class group of size one and no nontrivial everywhere-unramified abelian extension. A field with a nontrivial class group has a genuinely larger Hilbert class field. Computing ideals and their classes therefore reveals an extension field that may be difficult to write down directly.

Artin reciprocity and the existence theorem For a finite abelian extension L/F , the idelic norm map sends an idele of L to an idele of F . Class field theory states that the quotient

$$\theta_{L/F} : C_F / N_{L/F}(C_L) \longrightarrow \mathrm{Gal}(L/F)$$

is a canonical isomorphism. The map is the Artin reciprocity map. In the unramified prime case, it sends the class of a prime to its Frobenius automorphism, so the abstract map connects arithmetic with the way that prime acts on the roots of a polynomial modulo that prime. [1, 4]

The existence theorem says that finite abelian extensions of F correspond bijectively to closed subgroups of finite index in C_F . The subgroup attached to L is the norm group $N_{L/F}(C_L)$. In one direction, the extension produces a subgroup. In the other, a suitable subgroup produces a unique class field. This is why the theory is called class field theory: a class or subgroup of the arithmetic object determines a field.

The formulation also has an infinite version. The Galois group of the maximal abelian extension is naturally the profinite completion of C_F . Equivalently, the abelianization of the absolute Galois group is determined by the arithmetic class group. This unifies all finite abelian extensions instead of studying them one at a time. [1, 5]

Local and global reciprocity Local class field theory begins with a local field K . It gives a reciprocity isomorphism from $K^\times$ to the Galois group of its maximal abelian extension, interpreted with the correct profinite topology. The norm subgroup of a finite abelian extension L/K is the kernel of the corresponding map. Local units describe the part of the extension that is ramified, while the valuation records the unramified direction.

To pass from local to global theory, complete a number field at every place and apply the local maps. Their product is trivial on a global element embedded diagonally in all local fields. This is the global reciprocity law. It generalizes the product formula and reaches far beyond quadratic reciprocity: local contributions at all primes and at infinity fit together to produce one global statement. [1, 3]

There are two broad proof styles. Artin and Tate developed a cohomological method using group cohomology and class formations. It gives a powerful conceptual organization of norms, extensions, and obstructions. Later, Neukirch and others developed more explicit and algorithmic approaches that avoid some cohomology, making the reciprocity maps easier to calculate in examples. The two approaches prove the same central results but illuminate different parts of the subject. [3, 6]

Explicit class field theory General class field theory tells us that extensions exist and what arithmetic group controls them. Explicit class field theory tries to write the extensions down.

The Kronecker–Weber theorem says that every finite abelian extension of $\mathbb{Q}$ is contained in a cyclotomic field $\mathbb{Q}(\zeta_n)$, where ζ_n is an n th root of unity. Thus roots of unity generate all abelian extensions of the rational numbers. For example, the quadratic field $\mathbb{Q}(i)$ lies in $\mathbb{Q}(\zeta_4)$, and the real quadratic field $\mathbb{Q}(\sqrt{5})$ lies in the maximal real subfield of $\mathbb{Q}(\zeta_5)$. [1, 4]

For imaginary quadratic fields, elliptic curves with complex multiplication give another explicit source. Torsion points of these curves and special values of modular functions generate abelian extensions. Shimura’s theory extends this explicit viewpoint to broader classes of fields. In positive characteristic, cyclotomic and Drinfeld-module constructions provide parallel descriptions, and Witt duality gives a particularly direct description of the p -part of reciprocity in some settings. [4]

These explicit constructions are powerful but special. Roots of unity are naturally available over $\mathbb{Q}$, and complex multiplication supplies extra structure for imaginary quadratic fields. A general number field usually lacks such a visible source of generators, which is why the idelic formulation is needed.

Applications, boundaries, and generalizations Class field theory explains how primes split, remain inert, or ramify in abelian extensions. The Frobenius map turns this into arithmetic data that can be used to test congruences and factorization patterns. The theory is also used in Iwasawa theory, Galois module theory, Artin–Verdier duality, and explicit studies of special values of L -functions. Many advances toward the Langlands correspondence, the Birch and Swinnerton-Dyer conjecture, and Iwasawa theory use explicit class field methods or their extensions. [1, 7]

Class field theory deliberately treats the abelian case. Nonabelian Galois groups do not fit into the same simple correspondence with subgroups of an abelian class group. The Langlands program is often viewed as a proposed nonabelian class field theory, but it does not currently provide the same existence theorem for class fields. Anabelian geometry asks whether a number field or a hyperbolic curve can be reconstructed from its full absolute Galois group or algebraic fundamental group. Higher class field theory studies abelian

extensions of higher local and global fields; its arithmetic groups are higher K -groups such as Milnor K -groups rather than only $K_1 = K^\times$. [1, 8]

Class field theory depends on field theory, Galois theory, ideals, prime factorization, completions, topological groups, and group cohomology. It helps algebraic number theory by providing a complete abelian extension dictionary. It also supplies the abelian base case for the Langlands program, local tools for arithmetic geometry, and explicit reciprocity laws used in the study of elliptic curves and L -functions.

4. Important theorems and results

1. **Hilbert class field theorem.** For a number field F , the Galois group of its maximal everywhere-unramified abelian extension is canonically isomorphic to the ideal class group of F . [1]
2. **Artin reciprocity law.** For every finite abelian extension L/F , the quotient $C_F/N_{L/F}(C_L)$ is canonically isomorphic to $\text{Gal}(L/F)$. [1, 3]
3. **Existence theorem.** Finite abelian extensions of F correspond to closed finite-index subgroups of the idele class group C_F . [1]
4. **Kronecker–Weber theorem.** Every finite abelian extension of $\mathbb{Q}$ is contained in a cyclotomic field. [4]
5. **Chebotarev density theorem.** In a finite Galois extension, prime ideals are distributed among Frobenius conjugacy classes with densities determined by the sizes of those classes. In the abelian case, this turns reciprocity classes into predictable families of primes. [2]

Applications

1. **Cryptographic protocols using class groups.** Class groups of imaginary quadratic fields provide abelian groups of unknown structure, which is a desirable foundation for cryptographic constructions. The group $\text{Cl}(\mathbb{Q}(\sqrt{-d}))$ is hard to compute explicitly for large square-free d , yet its order and structure can be verified using class field theory’s prediction that the Hilbert class field has Galois group isomorphic to $\text{Cl}(\mathbb{Q}(\sqrt{-d}))$. Cryptosystems based on this

hardness include commitment schemes, verifiable delay functions, and group-action-based protocols analogous to Diffie–Hellman: two parties publicly exchange ideal classes and combine them with their secret ideals, arriving at a shared class without revealing the underlying ideals. The security rests on the assumption that computing the class number or finding a principal ideal representation is computationally intractable for appropriately chosen discriminants [1, 4].

2. **Primality proving via class field theory.** The theory of complex multiplication gives an explicit construction of abelian extensions of imaginary quadratic fields, and the resulting class polynomials can be used to prove that an integer is prime. Specifically, one computes the Hilbert class polynomial $H_d(X)$ for discriminant $-d$ and verifies that a given elliptic curve E over $\mathbb{F}_p$ has j -invariant equal to a root of $H_d(X)$ modulo p . Class field theory guarantees that p splits completely in the Hilbert class field $\mathbb{Q}(\sqrt{-d}, E)$ only when p is prime and satisfies the splitting conditions predicted by Artin reciprocity. This method, implemented in software such as APRCL and CM-based primality tests, proves primality of numbers with thousands of digits and is part of the infrastructure used by cryptographic libraries to generate large prime moduli for RSA and Diffie–Hellman key exchange [2, 3].
3. **Ideal class group and arithmetic dynamics.** The growth of denominators in orbits of rational points under polynomial iteration is governed by height functions whose local components are determined by splitting behavior in abelian extensions. Class field theory predicts how primes ramify or remain inert in these extensions, which in turn controls the canonical height that measures orbit growth. This connection has been used to prove that certain polynomial maps have only preperiodic rational points—a dynamical analogue of the Mordell conjecture—by reducing the height computation to Artin reciprocity and Chebotarev density arguments [1, 7].

6. Connections

Using existing theories

1. Galois theory supplies extension groups, algebraic number theory supplies ideals and units, and local fields supply completions at primes and infinite places.
2. Topological groups and harmonic analysis are needed because the relevant global Galois groups are profinite and the idele class group is topological.

Helping other theories

1. Class field theory helps arithmetic geometry and Diophantine analysis by predicting how primes split in extensions.
2. Its reciprocity map also provides the abelian part of the wider Langlands viewpoint, where arithmetic information is related to representations and analytic functions.

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

1. **Exercise 1.** What does the ideal class group measure?

Solution. It measures the failure of unique factorization of ideals into principal ideals. Two ideals have the same class when their quotient is principal. The group is finite for a number field, and its size is the class number.

2. **Exercise 2.** Why is $\mathbb{Q}(i)$ an example related to the Kronecker–Weber theorem?

Solution. Since $i = \zeta_4$ is a fourth root of unity, $\mathbb{Q}(i) = \mathbb{Q}(\zeta_4)$ is itself cyclotomic. The theorem says that every finite abelian extension of $\mathbb{Q}$, not just this example, is contained in some cyclotomic field.

3. **Exercise 3.** If a prime is unramified in an abelian extension, what arithmetic object describes its action?

Solution. The prime ideal determines a Frobenius automorphism in the Galois group. Artin reciprocity identifies this automorphism with the image of the prime's ideal class under the reciprocity map.

4. **Exercise 4.** What is the role of the norm subgroup $N_{L/F}(C_L)$?

Solution. It is the subgroup of the base idele class group made from norms of ideles upstairs. The quotient by this subgroup records exactly the abelian Galois symmetries of L/F .

5. **Exercise 5.** Why does class field theory not immediately solve arbitrary nonabelian extension problems?

Solution. The central arithmetic class groups and reciprocity quotients are abelian, so they naturally describe commuting Galois symmetries. A nonabelian extension contains additional ordering information that is not captured by these quotients. The Langlands program and anabelian geometry seek broader replacements.

Chapter 17

Cobordism theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. When should two spaces be regarded as the two ends of one larger space?

Formal

Cobordism compares manifolds by asking whether they jointly form the boundary of a compact manifold one dimension higher. It is a deliberately coarse comparison: two spaces that are not the same may still be connected by a higher-dimensional bridge. The resulting groups and rings can be calculated using surgery, Morse functions, characteristic numbers, and homotopy theory.

2. History

Historical development

1. The problem and the historical idea.

An n -dimensional manifold is a space that looks like ordinary $\mathbb{R}^n$ when viewed close to any one point. A surface is a two-dimensional manifold; a solid region is three-dimensional. A manifold with boundary is allowed to look like a half-space near its edge. A

compact manifold is one that is bounded and contains all its limiting points. A closed manifold is compact and has no boundary.

Classifying manifolds up to exact sameness is difficult. Two manifolds can have the same dimension and similar local appearance while differing globally in ways that are hard to detect. Cobordism asks a simpler question: can the two manifolds be placed together as the boundary of a compact manifold of one dimension higher? The higher-dimensional object is the cobordism. [1, 2]

The roots go back to Poincaré's attempts to understand homology through manifolds. Lev Pontryagin used the idea in geometric topology, and Rene Thom made the subject systematic. Thom showed that cobordism groups could be studied through homotopy theory and a construction now called the Thom space or Thom complex. This connected geometric questions with algebraic topology and helped establish cobordism as an extraordinary cohomology theory. [3, 4]

3. Theory

Core theory

Definition and elementary examples Two closed n -manifolds M and N are cobordant if there is a compact $(n + 1)$ -manifold W whose boundary is their disjoint union:

$$\partial W = M \sqcup N.$$

More precisely, a cobordism is a compact manifold W together with embeddings of M and N into its boundary whose images are disjoint and cover ∂W . The notation $(W; M, N)$ records the bridge and its two ends. The cobordism is not required to be connected.

The interval $[0, 1]$ is a one-dimensional cobordism between two points. For any closed manifold M , the cylinder $M \times [0, 1]$ is a cobordism between its two copies at the ends. A circle bounds a disk, so it is cobordant to the empty manifold and is called null-cobordant. Every sphere bounds a disk of one dimension higher. Every orientable closed surface bounds a handlebody, so it is null-cobordant in the unoriented setting.

The pair of pants is a two-dimensional cobordism: one circular boundary component at one end and two circles at the other. It models

splitting one loop into two. Reversing the direction models joining two loops. A disjoint union is cobordant to a connected sum; the bridge records the surgery that joins the pieces. These examples show why cobordisms are useful: they describe a controlled change rather than claiming that the endpoints are identical. [1, 5]

Cobordism is an equivalence relation on closed manifolds. Reflexivity comes from the cylinder, symmetry from turning W around, and transitivity from gluing two bridges along their common boundary. It is much coarser than homeomorphism or diffeomorphism. That coarseness is a strength: exact classification becomes impossible in many dimensions, while cobordism classes can often be calculated.

Unoriented, oriented, and structured versions In unoriented cobordism no direction is assigned to the manifolds. One may instead require orientations. The boundary orientation convention makes the two ends appear with opposite induced orientations, so an oriented cobordism from M to N has boundary $M \sqcup (-N)$. The oriented cobordism groups are written Ω_n^{SO} .

More generally, a manifold can carry a G -structure: extra data such as an orientation, a complex structure after stabilization, or a framing. The structure on the bridge must restrict to the given structures at its ends. Important choices include $G = O$ for unoriented cobordism, $G = SO$ for oriented cobordism, and $G = U$ for complex cobordism. Piecewise-linear and topological manifolds produce PL and TOP versions, which are generally harder to calculate than smooth versions. [3, 6]

Disjoint union gives addition. Cartesian product gives multiplication, because an m -manifold times an n -manifold has dimension $m + n$. Under suitable conditions the groups form a graded ring

$$\Omega_*^G = \bigoplus_{n \geq 0} \Omega_n^G.$$

The grading remembers dimension, and the ring records how geometric operations interact. This is already a useful summary: two manifolds may be compared by adding and multiplying their classes instead of manipulating every point.

Surgery: changing a manifold in a controlled way Surgery removes a standard piece and glues in a complementary piece. Suppose

an n -manifold contains an embedded

$$S^p \times D^q, \quad p + q = n,$$

where S^p is a p -sphere and D^q is a q -dimensional disk. Remove its interior and glue in

$$D^{p+1} \times S^{q-1}.$$

Their boundaries are both $S^p \times S^{q-1}$, so the gluing can be made along the common boundary. The result is another n -manifold, and the trace of the operation is an $(n + 1)$ -dimensional cobordism.

For a circle, cutting out two small intervals and joining the exposed endpoints can either leave one circle or produce two circles. For a sphere, removing a cylinder and inserting two disks gives two spheres; removing two disks and inserting a cylinder can give a torus or a Klein bottle depending on the gluing orientation. In higher dimensions surgery changes handles, holes, and sometimes the fundamental group while preserving the cobordism class. [1, 7]

Surgery is valuable because it turns a global classification problem into a sequence of local modifications. In high-dimensional topology, one first builds a manifold with desired algebraic invariants and then uses surgery to remove unwanted homotopy or homology. The h -cobordism theorem and the broader surgery program use this strategy to classify manifolds under strong hypotheses.

Morse functions and handle decompositions A Morse function is a smooth height function whose critical points are nondegenerate: near each critical point it looks like a sum of positive and negative squares. As the level of the function rises, the level surface changes only when it passes a critical point. A critical point of index $p + 1$ produces a p -surgery on the level manifold.

If $f : W \rightarrow [0, 1]$ is a Morse function on a cobordism with $f^{-1}(0) = M$ and $f^{-1}(1) = N$, then W is obtained from $M \times [0, 1]$ by attaching one handle for each critical point. A handle of index $p + 1$ has the form $D^{p+1} \times D^{n-p}$ and realizes the corresponding surgery. Conversely, a handle decomposition produces a suitable Morse function. This Morse–handle correspondence is one of the central practical tools of cobordism theory. [1, 7]

For example, a three-dimensional cobordism obtained by attaching a one-handle to a sphere can have a torus as its other boundary. The height function sees the attachment as a critical point of index one.

Instead of staring at the whole three-dimensional shape, one records the order and indices of the handles.

Cobordism as algebraic topology Thom's work identifies cobordism classes with homotopy classes of maps into Thom spaces. The details depend on the chosen structure, but the message is simple: a geometric object can be encoded by a map between standard spaces. This made calculation possible using homotopy theory, characteristic classes, and cohomology operations.

Cobordism is an extraordinary cohomology theory. Ordinary cohomology assigns groups to spaces using singular chains; extraordinary theories have different coefficient objects and detect geometric information that ordinary cohomology may miss. Complex K -theory and cobordism are important examples. Cobordism groups appear as coefficient groups of the corresponding generalized homology theory. [4, 6]

Characteristic numbers provide computable obstructions. A characteristic class is a cohomology class built from the tangent bundle of a manifold. Evaluating products of these classes on the fundamental class gives numbers. If two manifolds are cobordant, appropriate characteristic numbers agree. Conversely, in important settings, a complete list of characteristic numbers determines the cobordism class. This turns a geometric boundary question into arithmetic with integers.

Categories and quantum field theory Cobordisms themselves can be treated as morphisms in a category. The objects are closed manifolds; a morphism from M to N is a cobordism $(W; M, N)$. Composition is gluing: if W joins M to N and W' joins N to P , glue along N to obtain a cobordism from M to P . The common boundary is the interface at which the processes are joined.

This category is the geometric domain of a topological quantum field theory. An Atiyah–Segal type field theory assigns a vector space or other algebraic object to each boundary manifold and a linear map to each cobordism. The pair of pants becomes multiplication or comultiplication, while a cylinder acts as an identity. Because the assignment depends only on the topological cobordism, the resulting physical model ignores distances and angles but retains global topology. [8, 9]

What the theory depends on and where it is useful Cobordism theory depends on manifolds, boundaries, smooth maps, homotopy, homology, characteristic classes, and category theory. It helps Morse theory by translating critical points into handles, helps surgery theory by organizing changes of manifolds, and helps generalized cohomology by supplying geometric representatives for algebraic classes.

In geometric topology it gives a manageable equivalence relation for manifolds that cannot be classified exactly. In algebraic topology it supplies generalized homology and cohomology theories. In mathematical physics it gives the language for topological quantum field theory. In the Atiyah–Singer index theorem and Hirzebruch–Riemann–Roch, cobordism methods helped organize characteristic numbers and index calculations. [4, 8]

The limitations are instructive. Cobordism forgets much information: two manifolds may be cobordant while having different fundamental groups or geometries. A cobordism also need not be a product, so it need not give a deformation through identical-looking intermediate spaces. More refined theories, including h-cobordism, framed cobordism, and surgery theory, restore some of the information that ordinary cobordism discards.

4. Important theorems and results

1. **Equivalence theorem.** Cobordism is an equivalence relation on closed manifolds of a fixed dimension. The cylinder, reversal, and gluing give reflexivity, symmetry, and transitivity. [1]
2. **Morse–handle correspondence.** A Morse function on a cobordism gives a handle decomposition, and a handle decomposition comes from a suitable Morse function. Passing a critical point of index $p + 1$ performs a p -surgery. [7]
3. **Thom’s theorem.** Cobordism groups can be related to homotopy groups of Thom spaces, allowing geometric classification to be attacked with homotopy theory. [4]
4. **Characteristic-number principle.** In major smooth cobordism theories, characteristic numbers provide algebraic invariants that detect and, in appropriate settings, classify cobordism classes. [3]
5. **Cobordism-category principle.** Closed manifolds and cobor-

disms form a category under gluing, which is the input category for topological quantum field theories. [8]

5. Applications

Cobordism replaces direct manifold classification by boundary equivalence, characteristic numbers, and controlled higher-dimensional bridges.

1. Geometric topology
2. algebraic topology
3. manifold classification
4. surgery theory
5. generalized cohomology
6. topological quantum field theory
7. and mathematical physics.

6. Connections

Using existing theories

1. Differential topology supplies manifolds and smooth maps, algebraic topology supplies homotopy and homology, and Morse theory turns a manifold into handles attached at critical points.
2. Surgery then changes a manifold in controlled local steps while tracking the algebraic obstruction to success.

Helping other theories

1. Cobordism helps classify manifolds and organize generalized cohomology theories.
2. It also supplies the geometric language behind topological quantum field theory, where a manifold is viewed as a process between boundary manifolds and composition is given by gluing.

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

1. **Exercise 1.** Why are two copies of a closed manifold M cobordant?

Solution. The cylinder $M \times [0, 1]$ is compact and has boundary $M \times \{0\} \sqcup M \times \{1\}$. It is therefore a cobordism between the two copies.

2. **Exercise 2.** Show that the circle is null-cobordant.

Solution. The boundary of the disk D^2 is the circle S^1 . Taking one boundary component to be S^1 and the other to be empty gives a cobordism from the circle to the empty manifold.

3. **Exercise 3.** What does a critical point of Morse index $p + 1$ do to a level manifold?

Solution. It attaches a handle $D^{p+1} \times D^{n-p}$ to the cobordism. On the level set this removes $S^p \times D^{n-p}$ and inserts $D^{p+1} \times S^{n-p-1}$, which is p -surgery.

4. **Exercise 4.** Why is cobordism easier to classify than diffeomorphism in many dimensions?

Solution. Diffeomorphism requires matching the complete smooth structure. Cobordism only asks whether the two manifolds are the boundary of a higher-dimensional bridge, so many differences are ignored. The reduced information permits algebraic invariants and surgery calculations.

5. **Exercise 5.** How are two cobordisms composed?

Solution. Glue the outgoing boundary of the first cobordism to the incoming boundary of the second. The common manifold becomes an internal seam, and the result has the original incoming and outgoing boundaries.

Chapter 18

Coding theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How can a receiver recover an intended message after symbols are changed, lost, or observed by an adversary?

Formal

Coding theory designs representations of information for a particular purpose. Source coding removes unnecessary repetition to make data smaller; channel coding adds controlled repetition so errors can be detected and corrected; cryptographic coding protects information from adversaries; and line coding turns symbols into physical signals. A good code balances reliability, rate, delay, power, and computational effort.

2. History

Historical development

1. The communication problem and its history.

A message begins as information at a source. An encoder changes it into a string over an alphabet, such as the binary symbols 0 and 1. The string travels through a channel, where noise may

Figure 18.1: The same communication diagram explains compression, noise, redundancy, and recovery.

flip bits, erase symbols, add disturbances, or hide the signal. The decoder receives the damaged string and tries to recover the original message.

Coding theory asks how to design the encoder and decoder so that the result is efficient and reliable. It is studied in mathematics, information theory, electrical engineering, computer science, and linguistics. Its central tension is easy to state: removing redundancy saves space, while adding redundancy makes errors easier to detect. [1, 2]

Claude Shannon’s 1948 paper, *A Mathematical Theory of Communication*, supplied the statistical model and introduced entropy, mutual information, channel capacity, and the noisy-channel coding theorem. Shannon’s work explained the best possible rates even before practical codes were known. Richard Hamming developed error-detecting and error-correcting codes at Bell Labs. The binary Golay code followed in 1949. Later developments included the discrete cosine transform for JPEG, MPEG, and MP3, and modern turbo and low-density parity-check codes. [2, 3]

3. Theory

Core theory

Four kinds of coding Source coding, also called data compression, removes redundancy that is predictable from the source. DEFLATE, used in common compressed files, represents repeated patterns compactly. Lossless compression permits perfect reconstruction; lossy compression, used in images and sound, keeps the important perceptual information while discarding details.

Channel coding adds useful redundancy before transmission or storage. A compact disc uses Reed–Solomon coding and interleaving

so that a scratch affects different parts of the encoded word rather than destroying one contiguous block. Mobile phones combat radio noise and fading with channel codes. Modems and the NASA Deep Space Network use codes adapted to their different kinds of disturbances.

Cryptographic coding transforms information so that an unauthorized observer cannot read or alter it. Modern cryptography aims at confidentiality, integrity, authentication, and non-repudiation. It protects passwords, bank cards, electronic commerce, and network connections, and may be secure because of a computational assumption or, as with a one-time pad, secure even against unlimited computing power.

Line coding maps digital symbols to a physical waveform for base-band transmission. Unipolar, polar, bipolar, and Manchester encodings choose voltage changes so that a receiver can distinguish symbols, recover timing, and operate within the limits of the wire or radio channel. [1, 4]

Codes, alphabets, and distance Let $\mathcal{X}$ be the set of possible source messages and let Σ be a finite alphabet. A code is a function

$$C : \mathcal{X} \longrightarrow \Sigma^*,$$

where Σ^* denotes all finite strings over Σ . The string $C(x)$ is the codeword for message x , and its length is $l(C(x))$. If a random source symbol X has probability $\mathbb{P}[X = x]$, the expected code length is

$$l(C) = \sum_{x \in \mathcal{X}} l(C(x)) \mathbb{P}[X = x].$$

A code is non-singular when different source symbols receive different codewords. It is uniquely decodable when every concatenated sequence of codewords has only one possible splitting into source symbols. It is instantaneous, or prefix-free, when no codeword is a proper prefix of another; then the decoder can decide as soon as a codeword ends. These distinctions matter because a code that is individually unambiguous may still become ambiguous when codewords are placed next to one another. [1, 5]

For error correction, the Hamming distance between two equal-length words is the number of positions in which they differ. The minimum distance $d_{\min}$ of a code is the smallest distance between two distinct valid codewords. If a received word is closer to one valid

codeword than to all others, nearest-codeword decoding chooses that word.

Geometrically, codewords are points in a high-dimensional space. Large minimum distance puts them far apart, leaving room for noise to move a received word without crossing into a neighbor's region. The same picture connects coding with sphere packing: each codeword has a ball of correctable errors around it, and the balls must fit without overlapping.

Source coding and entropy Source coding tries to represent likely messages with short words and rare messages with longer words. A source's entropy is its average uncertainty. For a discrete source,

$$H(X) = - \sum_x \mathbb{P}[X = x] \log_2 \mathbb{P}[X = x].$$

If a source is highly predictable, its entropy is small and strong compression is possible. If all symbols are equally likely and independent, there is less redundancy to remove.

The source-coding theorem says that no lossless code can, in the long run, use fewer than approximately $H(X)$ bits per source symbol, while suitable codes can approach this limit. Huffman and arithmetic coding approach the limit for different source models. Run-length coding replaces a long sequence such as 000000 with a symbol saying “zero repeated six times.” The same idea appears in facsimile transmission and file compression.

The entropy bound is not a claim that every individual file has exactly its entropy as length. It is an average statement for long sequences under a chosen probability model. If the model is wrong, the promised savings may disappear. [2, 6]

Channel coding and error correction Suppose the message bit 0 is sent as 000 and 1 as 111. The two codewords have distance three. If at most one bit flips, the received word is closer to the correct codeword; for example, 101 is decoded as 111. This simple repetition code demonstrates the principle but wastes many bits.

In general, a code with minimum distance $d_{\min}$ detects up to $d_{\min} - 1$ errors and corrects up to

$$t = \left\lfloor \frac{d_{\min} - 1}{2} \right\rfloor$$

errors by nearest-neighbor decoding. Detection and correction are different goals: detecting an error may be enough if the sender can retransmit, while correction is necessary for one-way deep-space communication.

Interleaving spreads neighboring symbols across different codewords. A scratch on a CD then becomes many small errors, which a Reed–Solomon code can repair. Deep-space links face continuous thermal noise, telephone modems face network noise, and mobile radios face rapid fading. The best code depends on which error pattern is likely. [1, 7]

Algebraic and linear codes Algebraic coding theory expresses code properties using algebra. A linear block code is a set of fixed-length words over a finite field such that the sum of two codewords is again a codeword. It is often summarized by parameters $(n, k, d_{\min})$: n is the word length, k is the number of source symbols encoded at once, and $d_{\min}$ is the minimum Hamming distance. Its rate is k/n .

Examples include repetition, parity-check, cyclic, BCH, Hamming, Reed–Solomon, Reed–Muller, algebraic-geometric, perfect, and locally recoverable codes. A parity check can detect an odd number of bit errors. Hamming codes add several parity equations so that the pattern of failed checks, called the syndrome, identifies a single bad position.

Perfect codes fill the available error spheres exactly. The useful nontrivial examples include distance-three Hamming codes with parameters $(2^r - 1, 2^r - 1 - r, 3)$ and the binary $(23, 12, 7)$ and ternary $(11, 6, 5)$ Golay codes. The sphere-packing picture also reveals a limitation: as dimension grows, each codeword has many nearby neighbors, so even a small probability of choosing the wrong neighbor can accumulate. [1, 8]

Convolutional codes do not work on isolated blocks only. Each output symbol is a weighted sum of current and earlier input symbols stored in encoder registers. The encoder is often a small circuit of memory and exclusive-or gates. The Viterbi algorithm finds the most likely path through the encoder’s state diagram. Convolutional codes have been used in voiceband modems, GSM phones, satellite systems, and military communication. [7]

Cryptographic coding, synchronization, and shared channels

Cryptographic coding assumes that an adversary may listen to or modify a communication. Encryption hides the content; authentication

codes reveal whether the content was altered and identify the sender. Public-key systems allow secure exchange without first sharing a secret, while symmetric systems are usually faster once a key is available. Computationally secure systems depend on problems believed to be hard, such as factoring or discrete logarithms. A one-time pad gives information-theoretic security but requires a truly random key as long as the message and must never reuse it. [4]

Codes can also solve synchronization problems. A receiver must know where one message ends and the next begins, and must detect a phase shift or timing error. Special patterns allow the receiver to find alignment. Code-division multiple access assigns different, nearly uncorrelated sequences to users; after demodulation, the other users appear approximately as low-level noise, allowing several phones to share one radio channel.

Automatic repeat-request protocols add check bits and ask for retransmission when the checks fail. Internet protocols such as TCP use sequence numbers to distinguish a new packet from a retransmission. Thus coding is not only about correcting a corrupted symbol; it can coordinate the entire conversation between sender and receiver.

Group testing and other applications Group testing uses a code to find a small number of unusual items among a large population with as few tests as possible. A test pools several items and returns positive if at least one member has the property. The problem arose during the Second World War when pooled tests were considered for detecting syphilis among soldiers. Modern applications include defective-product screening, medical testing, compressed sensing, and identifying infected samples.

Analog coding studies error correction, compression, and encryption when signals are continuous rather than strings of bits. Neural coding asks how networks of neurons represent sensory information and how the nervous system may compress, detect, and correct signals. These fields show that coding ideas apply to physical and biological systems as well as digital computers. [9, 10]

How coding theory is used in real systems When a QR code is photographed at an angle or with a small stain, its added patterns let the reader recover missing modules. A compact disc survives dust because interleaving and Reed–Solomon checks turn a long scratch into a collection of repairable errors. A mobile phone chooses codes suited

to noise and fading, then changes its rate as the radio conditions change. A deep-space probe uses strong coding because a retransmission may take hours or years.

Compression and error correction are sometimes combined. A compressed file has little redundancy, so a few errors may make it unusable; a protected packet therefore adds redundancy after compression. The order matters: compressing after adding correction may destroy the patterns that the decoder needs. In storage, the design also balances capacity against lifetime, decoding energy, and the chance that multiple nearby bits fail together.

Coding theory depends on probability, logarithms, linear algebra, finite fields, algorithms, and signal models. It helps information theory by turning entropy and capacity bounds into practical constructions. It helps computer engineering by supplying decoders and storage protocols, cryptography by formalizing secure encodings, and statistics by providing designs for pooled tests and noisy observations. [2, 6]

4. Important theorems and results

1. **Source coding theorem.** For a memoryless source, the entropy is the fundamental lower limit on the average number of bits per source symbol for reliable lossless compression, and suitable codes approach this limit for long messages. [2]
2. **Noisy-channel coding theorem.** A noisy channel has a capacity; communication with arbitrarily small error probability is possible below that capacity, while reliable communication is impossible above it. [2]
3. **Distance bound.** A code with minimum distance $d_{\min}$ detects at most $d_{\min} - 1$ errors and corrects at most $\lfloor (d_{\min} - 1)/2 \rfloor$ errors by nearest-codeword decoding. [1]
4. **Hamming sphere-packing bound.** If a binary code corrects t errors, the radius- t error spheres around its codewords must be disjoint; this limits how many messages can be packed into a fixed word length. [1]
5. **Singleton bound.** A code with length n , size described by dimension k , and minimum distance d satisfies $d \leq n - k + 1$ in the standard linear setting. Codes meeting the bound, such as many

Reed–Solomon codes, are called maximum-distance separable. [8]

5. Applications

Hamming distance and entropy quantify redundancy, error correction, and the rate at which information can be transmitted reliably.

1. Data compression
2. mobile phones
3. QR codes
4. compact discs
5. hard drives
6. satellite and deep-space communication
7. computer networks
8. cryptography
9. medical testing
10. and neural information processing.

6. Connections

Using existing theories

1. Linear algebra supplies vector-space codes, algebra supplies finite fields and polynomial constructions, and probability models errors in a communication channel.
2. Information theory supplies entropy and capacity, which say how much compression or reliability is possible before a code is designed.

Helping other theories

1. Coding theory helps digital communication, storage, satellite links, and deep-space transmission by adding structured redundancy.

2. It also supports distributed storage and data integrity: a receiver can detect or repair errors because the valid messages occupy separated positions in a larger space.

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

1. **Exercise 1.** What is the Hamming distance between 101101 and 100001?

Solution. Compare positions: they differ in the third and fourth positions, and agree elsewhere. The distance is 2.

2. **Exercise 2.** How many errors can a code with minimum distance 7 detect and correct?

Solution. It can detect up to 6 errors. It can correct up to $\lfloor (7 - 1)/2 \rfloor = 3$ errors by nearest-codeword decoding.

3. **Exercise 3.** Decode 101 using the repetition code $\{000, 111\}$.

Solution. The distance from 101 to 000 is two, while its distance from 111 is one. Nearest-codeword decoding therefore returns 111, representing the message bit one.

4. **Exercise 4.** What do the parameters (n, k, d) of a linear block code mean?

Solution. The codeword has length n , k source symbols are encoded at once, and distinct codewords are at least distance d apart. The rate is k/n , while d controls error detection and correction.

5. **Exercise 5.** Why can interleaving help a Reed–Solomon code correct a scratch on a disc?

Solution. A scratch creates a burst of adjacent errors. Interleaving places adjacent stored symbols in different codewords, turning one burst into many smaller errors. Each codeword then stays within the correction ability of the Reed–Solomon decoder.

Chapter 19

Cohomology theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How can we turn local measurements into algebraic information about a whole space?

Formal

Cohomology assigns groups, rings, and other algebraic objects to spaces. A cohomology class records a pattern that is locally consistent but may fail to come from a simpler global choice. This makes cohomology a language for holes, twists, gluing obstructions, fields, and characteristic numbers.

2. History

Historical development

1. The central idea and history.

Suppose a surface looks ordinary in every small neighborhood but has a global twist. A strip made by joining the ends of a rectangle with one half-turn is a Mobius strip. Locally it looks like a rectangle, but globally it is not a cylinder. Cohomology records the obstruction to choosing one consistent description all the way around.

The word comes from homology, which counts holes using chains. Cohomology reverses the arrows: instead of building geometric pieces, it studies functions or measurements on those pieces. The theory grew from topology in the nineteenth and early twentieth centuries and became a central tool in geometry and algebra. Singular cohomology, de Rham cohomology, sheaf cohomology, and generalized cohomology theories now share a common pattern. [1, 4]

The advantage is computability. A difficult shape is replaced by groups and a product operation. A continuous map between spaces produces a map in the opposite direction on cohomology, so geometric relationships become algebraic equations that can be calculated.

3. Theory

Core theory

Cochains, coboundaries, and classes A cochain complex is a sequence of groups or vector spaces

$$C^0 \xrightarrow{d^0} C^1 \xrightarrow{d^1} C^2 \xrightarrow{d^2} \dots$$

in which two consecutive arrows compose to zero:

$$d^{n+1}d^n = 0.$$

The map d is called the coboundary operator. An element in $\ker d^n$ is a cocycle; it satisfies the consistency condition. An element in $\operatorname{im} d^{n-1}$ is a coboundary; it came from a simpler object one degree earlier. The n th cohomology group is

$$H^n(C^\bullet) = \ker(d^n) / \operatorname{im}(d^{n-1}).$$

Thus cohomology keeps consistent data and identifies two data sets when their difference is an elementary change.

For differential forms, the operator is ordinary differentiation. A form is closed when its derivative is zero and exact when it is the derivative of another form. Every exact form is closed, but a closed form need not be exact if the space has a hole. The quotient of closed forms by exact forms is de Rham cohomology.

On a circle, a periodic function has derivative with integral zero over one complete turn. The form $d\theta$ is closed but has integral 2π , so

it is not exact on the circle. Every one-form $g(\theta)d\theta$ differs from an exact form by a constant multiple of $d\theta$. Hence

$$H^0(S^1, \mathbb{R}) \cong \mathbb{R}, \quad H^1(S^1, \mathbb{R}) \cong \mathbb{R},$$

and higher groups vanish. The first group records the one independent circular direction. [2, 3]

Singular cohomology and functoriality For a topological space X , singular homology uses continuous maps from standard simplices into X . The groups of formal sums of these simplices form a chain complex with boundary maps. Singular cochains are homomorphisms from the chain groups to a coefficient group A . Dualizing the boundary maps gives coboundary maps, and their kernels modulo images define

$$H^n(X; A).$$

The coefficient group matters. Integer coefficients can detect torsion, while real or rational coefficients may simplify calculations and ignore some finite information.

A continuous map $f : X \rightarrow Y$ induces a pullback

$$f^* : H^n(Y; A) \longrightarrow H^n(X; A).$$

The direction reverses because a measurement on Y can be evaluated after sending a point of X to Y . Homotopic maps induce the same pullback, so cohomology is a topological invariant rather than an accidental feature of coordinates.

The cohomology groups usually form a graded-commutative ring under the cup product. Classes in degrees p and q multiply to a class in degree $p+q$. The product stores how different holes and measurements interact, which is why the cohomology ring can distinguish spaces with the same groups. [1, 5]

Computing cohomology The Mayer–Vietoris sequence breaks a space into overlapping parts. If $X = U \cup V$, the cohomology of U , V , and $U \cap V$ fit into a long exact sequence containing the cohomology of X . This is the algebraic version of solving a global problem by comparing local pieces.

Relative cohomology $H^n(X, Y; A)$ measures what remains in X after treating a subspace Y as trivial. It fits into a long exact sequence

with $H^n(X)$ and $H^n(Y)$. The universal coefficient theorem relates cohomology to homology:

$$0 \rightarrow \text{Ext}_{\mathbb{Z}}^1(H_{n-1}(X; \mathbb{Z}), A) \rightarrow H^n(X; A) \rightarrow \text{Hom}_{\mathbb{Z}}(H_n(X; \mathbb{Z}), A) \rightarrow 0.$$

Over a field, this reduces to the dual of homology as a vector space.

The diagonal in $X \times X$ is another important object. Its cohomology class encodes the identity map and is used in intersection theory and fixed-point formulas. The cap product pairs cohomology classes with homology classes, allowing a measurement to be evaluated on a geometric cycle. [1, 2]

Poincare duality and characteristic classes For a closed oriented n -manifold M , Poincare duality pairs degree k cohomology with degree $n - k$ homology. Geometrically, a k -dimensional measurement corresponds to an $(n - k)$ -dimensional complementary cycle. For an oriented surface, the class of a loop is paired with a class recording how another loop intersects it.

Characteristic classes are cohomology classes attached to vector bundles. A vector bundle assigns a vector space to every point in a continuous way, as the tangent planes of a surface do. Stiefel–Whitney, Chern, and Pontryagin classes detect whether a bundle can be oriented, trivialized, or given additional structure. Their products and evaluations give characteristic numbers that obstruct two manifolds or bundles from being equivalent.

These classes connect cohomology to geometry. The Euler class detects zeros of vector fields; Chern classes measure twisting of complex bundles; Pontryagin classes enter the signature theorem. In physics, gauge fields are connections on bundles and their global charges are expressed through characteristic classes. [3, 6]

Sheaf cohomology and algebraic geometry A sheaf assigns local data to each open region and specifies how data restricts to smaller regions. Sections may exist on every small patch but fail to glue consistently on the whole space. Sheaf cohomology measures exactly this failure. Degree zero records global sections; higher groups record increasingly subtle gluing obstructions.

This idea is fundamental in algebraic geometry. A line bundle may be locally described by one formula on each chart, while transition functions on overlaps twist the charts together. Sheaf cohomology

determines whether the bundle has global sections and counts them through Euler characteristics. It also appears in complex analysis, where the existence of a global solution to a local analytic problem becomes a cohomology question.

Cohomology of varieties includes singular, de Rham, étale, crystalline, and other theories. They use different kinds of coefficients and different geometric information, but they aim at the same kind of invariant: a computable record of global structure. [4, 7]

Axioms and generalized theories Ordinary cohomology satisfies the Eilenberg–Steenrod axioms: homotopy invariance, exactness, excision, additivity, and a dimension condition. If the dimension condition is removed, generalized or extraordinary cohomology theories appear. K-theory, cobordism, and stable cohomotopy are examples. They detect structure that ordinary cohomology cannot.

Eilenberg–Mac Lane spaces provide a bridge between cohomology and homotopy. A degree- n cohomology class can be represented by a homotopy class of maps into a suitable space $K(A, n)$. This gives a topological meaning to what otherwise looks like an algebraic quotient.

Cohomology theories are also used in group cohomology, Lie algebra cohomology, cyclic and Hochschild cohomology, Galois cohomology, and mathematical physics. The same pattern persists: consistent objects are divided by trivial changes, and the remainder records an obstruction or invariant. [4, 8]

What the theory depends on and where it is useful Cohomology depends on algebraic groups, linear maps, chain complexes, topology, differential forms, and integration. It helps homology by supplying dual measurements, helps homotopy theory by converting maps into algebraic invariants, and helps geometry by expressing twisting and intersection in equations.

In topology, the cohomology ring distinguishes spaces that have identical numbers of holes but different ways for those holes to interact. In differential geometry, de Rham cohomology turns global questions about differential equations into integrals. In algebraic geometry, sheaf cohomology controls global sections and the geometry of bundles. In physics, characteristic classes express quantized charges and obstructions to global gauge choices. The theory is useful precisely because local formulas are easy to write while global consistency is hard.

4. Important theorems and results

1. **Cochain-complex definition.** For $d^{n+1}d^n = 0$, the quotient $\ker d^n / \operatorname{im} d^{n-1}$ is the n th cohomology group. It measures consistent data modulo elementary changes. [1]
2. **Homotopy invariance.** Homotopic continuous maps induce the same map on cohomology. Therefore cohomology depends on the homotopy type of a space. [2]
3. **Mayer–Vietoris sequence.** The cohomology of a union can be calculated from the cohomology of two pieces and their intersection through a long exact sequence. [2]
4. **Poincare duality.** For a closed oriented n -manifold, degree k cohomology and degree $n - k$ homology are paired by evaluation on the fundamental class. [3]
5. **de Rham theorem.** The cohomology of smooth differential forms on a manifold is naturally isomorphic to its singular cohomology with real coefficients. [6]

5. Applications

Cocycles, coboundaries, and cup products convert local compatibility data into global algebraic invariants.

1. Algebraic topology
2. differential geometry
3. algebraic geometry
4. topology of manifolds
5. gauge theory
6. physics
7. and the classification of bundles and global structures.

6. Connections

Using existing theories

1. Algebraic topology supplies chains and boundaries, linear algebra turns them into kernels and quotients, and category theory explains functoriality and long exact sequences.
2. Differential geometry supplies de Rham forms, while algebraic geometry supplies sheaves and derived constructions.

Helping other theories

1. Cohomology helps topology detect holes, helps geometry solve global extension problems, and helps number theory organize arithmetic information.
2. Its functorial maps and duality statements let different theories transfer local calculations into global conclusions.

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

1. **Exercise 1.** Why is every exact differential form closed?

Solution. If $\omega = df$, then $d\omega = d(df) = 0$ because applying the exterior derivative twice gives zero. Hence exact forms lie inside the closed forms.

2. **Exercise 2.** Why is $d\theta$ on a circle not exact?

Solution. If it were df for a globally defined periodic function, its integral around the circle would be $f(2\pi) - f(0) = 0$. But $\int_0^{2\pi} d\theta = 2\pi$. Therefore it is closed but not exact and represents a nonzero class.

3. **Exercise 3.** What does a pullback do to a cohomology class?

Solution. A map $f : X \rightarrow Y$ takes a measurement or differential form defined on Y and evaluates it after applying f . This produces a class on X , giving $f^* : H^n(Y) \rightarrow H^n(X)$.

4. **Exercise 4.** What information does the cup product add?

Solution. It records how classes in different degrees combine. Two spaces may have the same cohomology groups but different products, so the ring structure can distinguish their global geometry.

5. **Exercise 5.** What is a gluing obstruction?

Solution. It is local data that is compatible on overlaps but cannot be produced by one global choice. Sheaf cohomology records the obstruction and can show whether a global section, solution, or bundle trivialization exists.

Chapter 20

Continuum theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How can we study connected shapes that are too irregular to be treated as smooth curves or surfaces?

Formal

A continuum is a nonempty compact connected metric space, or in a broader version a compact connected Hausdorff space. Continuum theory studies the subcontinua, decompositions, inverse limits, and symmetries of such spaces. It provides a language for wild and fractal-like shapes without requiring coordinates or differentiability.

2. History

Historical development

1. Hans Hahn and Stefan Mazurkiewicz.

They established foundational results about connected compact metric spaces and about continuous images of intervals. These results supplied basic models and structural tests for continua.

2. Gordon T. Whyburn and later continuum theorists.

Whyburn developed decomposition and separation methods for continua. Later researchers used inverse limits and decompositions to construct and analyze connected spaces with wild local behavior.

3. Theory

Core theory

Why continua matter The interval $[0, 1]$, a circle, a disk, a tree-shaped network, and the Sierpinski carpet are all examples of connected shapes. A topologist may care about whether a shape stays connected after a piece is removed, whether every pair of points can be joined by a path, and whether the shape can be decomposed into simpler connected pieces.

Smooth geometry is not enough for many examples. A fractal may have infinitely many branches or no tangent line at many points. Continuum theory studies the shape using only stable topological properties: compactness, connectedness, continuous maps, and the arrangement of subspaces. The subject grew in point-set topology and geometric topology and is also used in topological dynamics, where an interval-like state space evolves under repeated maps. [1, 2]

Definition and basic vocabulary A continuum is a nonempty compact connected metric space. Compactness means that every sequence has a convergent subsequence with its limit still in the space, while connectedness means that the space cannot be split into two disjoint nonempty open pieces. Some authors use compact connected Hausdorff spaces instead of metric spaces.

A continuum containing more than one point is nondegenerate. A subset A of a continuum X is a subcontinuum when A is itself a continuum with the subspace topology. A planar continuum is a space homeomorphic to a subcontinuum of the Euclidean plane.

The interval is an arc; a circle is a simple closed curve. A continuum is locally connected if each point has arbitrarily small connected neighborhoods. A locally connected continuum is often called a Peano continuum. Local connectedness is stronger than connectedness: the topologist's sine curve is connected but has a complicated failure of local connectedness.

A continuum is homogeneous if for every two points x, y there is a homeomorphism of the whole continuum sending x to y . A circle

is homogeneous; a usual interval is not because its endpoints have a different local role from interior points. An indecomposable continuum cannot be written as the union of two proper subcontinua. Such spaces demonstrate how far connected sets can be from ordinary curves. [1, 3]

Connectedness is not path connectedness A path is a continuous map from $[0, 1]$ to the space. Path connectedness requires a path between every pair of points. Every path-connected space is connected, but the reverse implication fails. The topologist's sine curve and related examples are connected although some pairs of points cannot be joined by a path.

This distinction matters in applications. A model may have no sudden separation into two regions while still lacking a usable route between two states. Continuum theory keeps these questions separate rather than replacing all kinds of connectedness by one word.

Continuous images preserve the defining properties: the continuous image of a compact space is compact, and the continuous image of a connected space is connected. Therefore a continuous image of a continuum is a continuum. A projection, deformation, or limit map can simplify a shape without destroying its continuum status. [2]

Constructing continua by nested intersections One fundamental construction uses a nested sequence

$$X_1 \supseteq X_2 \supseteq X_3 \supseteq \cdots$$

of continua. If every X_n is nonempty, compact, and connected, then

$$X = \bigcap_{n=1}^{\infty} X_n$$

is nonempty, compact, and connected. The intersection may be much more complicated than any one stage.

This construction explains how a fractal can be built. Begin with a connected compact set, remove selected pieces while preserving connectedness or a controlled collection of components, and repeat. The limiting set can have infinitely many holes, branches, or boundary details. The theorem guarantees that the limit remains a continuum when the nested pieces obey the hypotheses.

Products supply another construction. A finite or countable product of continua is a continuum in the standard product topology. The

product of two intervals is a square, while infinite products create compact connected spaces with infinitely many coordinates. [1, 4]

Inverse limits An inverse sequence consists of continua $X_1, X_2, \dots$ and continuous bonding maps

$$f_n : X_{n+1} \longrightarrow X_n.$$

The inverse limit is the set of compatible choices

$$\varprojlim (X_n, f_n) = \{(x_1, x_2, \dots) : f_n(x_{n+1}) = x_n \text{ for every } n\}.$$

It is a subset of the product of all coordinate spaces. Compatibility says that the description at a later, more detailed stage agrees with the description seen at an earlier stage.

The inverse limit of a sequence of continua is again a continuum under standard compactness assumptions. This is a powerful way to construct spaces that are not simple subsets of the plane. For example, inverse limits of intervals under a map can produce indecomposable continua and spaces that arise naturally as invariant sets in dynamical systems.

The method also explains approximation. A complicated limit object is represented by a sequence of simpler coordinate spaces and maps. Instead of drawing the limit exactly, one studies the finite stages and checks that the compatibility maps preserve the needed properties. [1, 5]

Decompositions, planar continua, and dynamics A decomposition divides a continuum into subcontinua. The quotient space records which points have been identified as belonging to one piece. Questions include whether the quotient is again a well-behaved continuum, whether the pieces vary continuously, and whether the original space can be reconstructed from them.

Planar continua include boundaries of regions, dendrites, lakes of Wada, and many fractal sets. A dendrite is a locally connected continuum containing no simple closed curve; it behaves like a tree that may branch infinitely often. The Menger sponge is a three-dimensional universal compact space for many embedding questions, while planar continua expose restrictions caused by the plane.

In topological dynamics, a continuous map $T : X \rightarrow X$ moves points of a continuum through time. An invariant continuum satisfies

$T(X) = X$ or contains a dynamically preserved subcontinuum. Inverse limits and continua are used to describe attractors, interval maps, and complicated invariant sets. A continuum may remain connected even while the individual trajectories are chaotic. [5, 6]

What the theory depends on and where it is useful Continuum theory depends on metric spaces, compactness, connectedness, continuous maps, homeomorphisms, product topology, and inverse limits. It helps topological dynamics by describing state spaces and invariant sets, helps shape theory by retaining information when a space is too wild for ordinary homotopy methods, and helps geometric topology by classifying embeddings and decompositions.

The theory is useful whenever the shape is more important than a coordinate formula. It can model a branching physical object, a limiting construction, or an invariant set from a dynamical system. Its limitations are clear: continua need not be smooth, locally connected, path connected, or easy to visualize, and many classification problems remain open. These difficulties are not defects in the definition; they are the reason a general theory is needed.

4. Important theorems and results

1. **Continuous-image theorem.** The continuous image of a continuum is a continuum. Compactness and connectedness are both preserved by continuous maps. [2]
2. **Nested-intersection theorem.** The intersection of a nested nonempty family of compact connected sets is a continuum when the standard compactness hypotheses hold. [1]
3. **Inverse-limit theorem.** The inverse limit of a sequence of continua with continuous bonding maps is a continuum under the usual nonemptiness and compactness assumptions. [1]
4. **Product theorem.** A finite or countable product of continua is a continuum in the product topology. [4]
5. **Peano continuum principle.** Local connectedness gives much stronger control over arcs and neighborhoods than connectedness alone; its failure explains important wild continua. [3]

5. Applications

Compactness and connectedness, refined by inverse limits and decompositions, describe spaces whose geometry is too wild for coordinates alone.

1. Point-set topology
2. geometric topology
3. topological dynamics
4. fractal geometry
5. inverse limits
6. and the study of complicated connected shapes.

6. Connections

Using existing theories

1. Point-set topology supplies compactness, connectedness, and continuous maps; metric spaces provide concrete examples and inverse limits provide a way to build complicated continua from simpler ones.
2. Dimension theory and planar topology refine the basic question of how a connected compact set can be shaped.

Helping other theories

1. Continuum theory helps geometric topology and dynamical systems describe invariant compact sets.
2. It also supplies counterexamples that test whether a proposed theorem really needs local connectedness, path connectedness, or a dimension assumption.

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

1. **Exercise 1.** Why is $[0, 1]$ a continuum?

Solution. It is nonempty, compact in the usual metric, and connected because it cannot be separated into two disjoint nonempty open subsets.

2. **Exercise 2.** Why is the rational interval $\mathbb{Q} \cap [0, 1]$ not a continuum?

Solution. It is not compact in the subspace topology: a sequence of rationals can converge to an irrational number in $[0, 1]$, whose limit is missing. It is also totally disconnected.

3. **Exercise 3.** What does homogeneity mean for a continuum?

Solution. Every point can be moved to every other point by a homeomorphism of the entire space. The circle is homogeneous, but an interval is not because an endpoint cannot be mapped to an interior point while preserving local structure.

4. **Exercise 4.** What is an inverse-limit point?

Solution. It is a sequence $(x_1, x_2, \dots)$ with $x_n \in X_n$ such that $f_n(x_{n+1}) = x_n$ for every n . Each coordinate is a consistent view of the same limiting object.

5. **Exercise 5.** Why can connectedness fail to provide a path?

Solution. Connectedness only forbids a separation into two open pieces. A path requires a continuous parametrized route between every pair of points. Wild continua can satisfy the first condition but not the second.

Chapter 21

Computational learning theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How much data is needed to learn a concept, and when can a concept be learned efficiently?

Formal

Computational learning theory studies what can be inferred from examples and how much evidence is needed. It asks whether a learner can find a hypothesis that is probably approximately correct, how many samples suffice, and what properties of a concept class determine its learnability.

2. History

Historical development

1. The learning problem.

A learner receives examples of an unknown function f drawn from a fixed but unknown distribution $\mathcal{D}$ over an instance space $\mathcal{X}$. The learner chooses a hypothesis h from a hypothesis class $\mathcal{H}$. The

error of h is the probability that $h(x) \neq f(x)$ when x is drawn from $\mathcal{D}$. The learner does not know $\mathcal{D}$ or f ; it sees only a finite sample. The central question is how large that sample must be so that the chosen h has small error with high probability.

2. Historical development.

(a) Origins in psychology and philosophy.

The problem of learning from examples is older than its mathematical formulation. William of Ockham suggested in the fourteenth century that the simplest explanation consistent with observations is preferred. In the twentieth century, questionnaires about concept acquisition led to early artificial intelligence systems that tried to infer rules from positive and negative examples.

(b) Valiant's PAC framework.

Leslie Valiant proposed the Probably Approximately Correct model in 1984. He defined learnability as a complexity question: a concept class is learnable when a learner can, from a polynomial number of examples, produce a hypothesis whose error is below a chosen tolerance with high probability. This made learning a topic of computational complexity theory [1].

(c) VC theory.

Vladimir Vapnik and Alexey Chervonenkis introduced the dimension that bears their name in 1971. The VC dimension measures the largest set of points that a hypothesis class can shatter, meaning it can realize every possible labeling of those points. It controls sample complexity: a class with finite VC dimension needs only finitely many examples to learn, regardless of the distribution.

(d) Online learning and boosting.

In the 1990s, online learning models received new attention. The weighted majority algorithm and its variants combined weak learners into strong ones. Robert Schapire and Yoav Freund developed AdaBoost, which provably reduces error by combining classifiers that are only slightly better than random guessing. These results connected computational learning theory with practical machine learning [3].

(e) **Contemporary directions.**

Modern work extends the PAC framework to distribution-free settings, to classes with infinite VC dimension measured by Rademacher complexity, to agnostic learning where no target concept in the class is assumed, and to statistical learning theory where the emphasis is on generalisation bounds rather than computational efficiency [2].

3. Theory

Core theory

3. The PAC model.

In the PAC model, the learner receives m independent examples $(x_i, f(x_i))$ drawn from $\mathcal{D}$. It outputs a hypothesis $h \in \mathcal{H}$. The hypothesis has error $\text{err}(h) = \Pr_{x \sim \mathcal{D}}[h(x) \neq f(x)]$. The learner is probably approximately correct when for every $\varepsilon, \delta > 0$, it produces h with $\text{err}(h) \leq \varepsilon$ with probability at least $1 - \delta$, provided the sample size m is large enough.

The sample complexity is the minimum m that guarantees this. For a finite hypothesis class $\mathcal{H}$ and a realisable setting where the target f belongs to $\mathcal{H}$, the bound

$$m \geq \frac{1}{\varepsilon} \left(\ln |\mathcal{H}| + \ln \frac{1}{\delta} \right)$$

suffices. It follows from a union bound: each bad hypothesis can be eliminated by seeing a counterexample, and the number of hypotheses is $|\mathcal{H}|$.

4. VC dimension.

When $\mathcal{H}$ is infinite, VC dimension replaces $|\mathcal{H}|$. A set of points $S = \{x_1, \dots, x_n\}$ is shattered by $\mathcal{H}$ when for every subset $T \subseteq S$, there exists $h \in \mathcal{H}$ such that $h(x_i) = 1$ if and only if $x_i \in T$. The VC dimension $\text{VC}(\mathcal{H})$ is the largest n for which some set of size n is shattered.

A half-plane in $\mathbb{R}^2$ has VC dimension three: it can shatter any three non-collinear points but cannot shatter four. The growth function

$\Pi_{\mathcal{H}}(m)$ counts the number of distinct labelings that $\mathcal{H}$ produces on m points. Sauer's lemma bounds it:

$$\Pi_{\mathcal{H}}(m) \leq \sum_{i=0}^{\text{VC}(\mathcal{H})} \binom{m}{i} \leq \left(\frac{em}{\text{VC}(\mathcal{H})} \right)^{\text{VC}(\mathcal{H})}.$$

This implies that $\mathcal{H}$ shatters at most a polynomial number of labelings even when it is infinite, so the sample bound generalises:

$$m \geq C \frac{\text{VC}(\mathcal{H}) \ln(1/\varepsilon) + \ln(1/\delta)}{\varepsilon^2}$$

examples suffice for PAC learning [2].

5. Rademacher complexity.

Rademacher complexity measures the richness of a hypothesis class by how well it can fit random noise. For a sample $S = (x_1, \dots, x_m)$ and a class $\mathcal{H}$ of real-valued functions, the empirical Rademacher complexity is

$$\hat{\mathfrak{R}}_S(\mathcal{H}) = \mathbb{E}_{\sigma} \left[\sup_{h \in \mathcal{H}} \frac{1}{m} \sum_{i=1}^m \sigma_i h(x_i) \right],$$

where σ_i are independent Rademacher random variables taking values ± 1 with equal probability. A generalisation bound of the form

$$\text{err}(h) \leq \text{err}(h) + 2\hat{\mathfrak{R}}_S(\mathcal{H}) + \sqrt{\frac{\ln(1/\delta)}{2m}}$$

holds simultaneously for all $h \in \mathcal{H}$ with probability at least $1 - \delta$. When $\mathcal{H}$ consists of linear classifiers in $\mathbb{R}^d$ with bounded norm, $\hat{\mathfrak{R}}_S(\mathcal{H})$ is of order $\sqrt{d/m}$, giving a parametric rate even when the class is infinite [4].

6. Agnostic learning.

In agnostic learning, the target f may not belong to $\mathcal{H}$. The best achievable error is

$$\text{err}^* = \inf_{h \in \mathcal{H}} \text{err}(h).$$

A learner is agnostically PAC when it finds h with $\text{err}(h) \leq \text{err}^* + \varepsilon$ with high probability. The sample complexity depends on the pseudo-dimension of $\mathcal{H}$, a generalisation of VC dimension for real-valued function classes. Agnostic learning is harder than realisable

learning: without the assumption that $f \in \mathcal{H}$, more examples are needed and the hypothesis class must satisfy additional structural conditions such as convexity or finite metric entropy [2].

7. Boosting.

Boosting combines many weak learners, each slightly better than random, into a single strong learner. AdaBoost maintains a distribution over training examples, focusing on those that the current ensemble misclassifies. After T rounds, the combined hypothesis has error

$$\text{err} \leq \prod_{t=1}^T 2\sqrt{\varepsilon_t(1 - \varepsilon_t)},$$

where ε_t is the weighted error of the t -th weak learner. If each weak learner has error below $1/2 - \gamma$, the product decreases exponentially with T . Schapire showed that boosting is possible in principle; Freund and Schapire gave a practical algorithm. The connection to margin theory explains why boosting often improves generalisation even when training error reaches zero [3].

8. Online learning and regret minimization.

In online learning, examples arrive one at a time and the learner must predict before seeing the label. Regret compares the learner's cumulative loss with the best fixed hypothesis in hindsight. The weighted majority algorithm achieves regret $O(\sqrt{T \ln |\mathcal{H}|})$ over T rounds. The hedge algorithm and follow-the-regularised-leader extend this to infinite strategy sets. Online-to-batch conversion turns an online algorithm with low regret into a batch learner with good generalisation [5].

9. Computational efficiency.

PAC learning requires the hypothesis to have low error, but it does not require the learner to run in polynomial time. Proper PAC learning requires outputting a hypothesis from $\mathcal{H}$; improper learning allows outputting any computable function. Some classes are efficiently improperly learnable but not efficiently properly learnable. The relationship between computational and statistical complexity remains a central open question: many classes with finite VC dimension are statistically learnable but not known to be computationally learnable in polynomial time [1].

10. Applications.

In machine learning, PAC bounds guide model selection and tell practitioners how much data is needed. In natural language processing, VC bounds on recurrent networks help estimate sample requirements. In computational biology, learning theory explains why gene-expression classifiers need many samples when the number of features is large. In economics and game theory, online learning models describe how agents improve strategies through repeated interaction. In computer vision, sample complexity bounds explain the data hunger of deep networks and motivate data augmentation [4].

11. What the theory depends on and where it is useful.

Computational learning theory depends on probability, combinatorics, linear algebra, optimisation, and computational complexity. It helps statistics quantify generalisation, machine learning guide model choice, and computer science separate tractable from intractable learning problems. Its bounds are often conservative: they hold for the worst case over distributions, so practical learning may need fewer examples than the theory guarantees.

4. Important theorems and results

- (a) **Fundamental theorem of PAC learning.** A finite hypothesis class is PAC learnable if and only if it is finite, and the sample complexity is $\Theta((\ln |\mathcal{H}| + \ln(1/\delta))/\varepsilon)$ in the realisable case [1].
- (b) **VC dimension theorem.** A hypothesis class with VC dimension d is PAC learnable with sample complexity $\Theta((d + \ln(1/\delta))/\varepsilon^2)$ in the realisable case and $\Theta((d + \ln(1/\delta))/\varepsilon^2)$ in the agnostic case [2].
- (c) **Sauer's lemma.** The growth function of a class with VC dimension d is bounded by $(em/d)^d$, ensuring that finite VC dimension implies finite sample complexity [2].
- (d) **No-free-lunch theorem.** Without assumptions on the target distribution, no learner can guarantee error below $1/2$ for all possible target functions. Every PAC learning result requires

either a restricted hypothesis class or a restriction on the data-generating process [1].

- (e) **Boosting theorem.** Any weak learner that produces hypotheses with edge γ over random guessing can be boosted into a strong learner with arbitrarily small error by running AdaBoost for $O(\ln(1/\varepsilon)/\gamma^2)$ rounds [3].

5. Applications

Sample complexity, VC dimension, and Rademacher complexity measure how much data a concept class needs before a learner can generalise reliably.

- (a) Machine learning
- (b) statistics
- (c) data mining
- (d) artificial intelligence
- (e) computer vision
- (f) natural language processing
- (g) bioinformatics
- (h) and economics.

6. Connections

Using existing theories

- (a) Probability supplies concentration inequalities and Rademacher complexity, while statistics provides hypothesis testing and confidence bounds that compare with PAC guarantees.
- (b) Computational complexity separates tractable from intractable learning problems, and information theory bounds the rate at which a learner can reduce uncertainty.

Helping other theories

- (a) Computational learning theory helps machine learning estimate how much data is needed, guides model selection, and explains why boosting, regularisation, and margin maximisation work.
- (b) It also connects to online optimisation, game theory, and control by analysing how agents improve through repeated interaction and feedback.

7. Sample Questions

Exercise reference: [2]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1.** Define the PAC learning model and explain the roles of ε and δ .

Solution. In the PAC model, the learner receives m examples of an unknown function drawn from a fixed distribution. It outputs a hypothesis whose error is at most ε with probability at least $1 - \delta$. The parameter ε controls accuracy and δ controls confidence.

- (b) **Exercise 2.** What is the VC dimension of intervals on the real line?

Solution. The VC dimension is 2. Two points can be shattered: an interval can include either, both, or neither. Three points cannot always be shattered because the middle point cannot be excluded while including both outer points.

- (c) **Exercise 3.** How does the no-free-lunch theorem limit what a learner can guarantee?

Solution. Without assumptions on the target or the distribution, no learner can achieve error below $1/2$ for all possible target functions. Every positive learning result requires some restriction, such as a finite hypothesis class, a bounded VC dimension, or an assumption that the target belongs to the class.

- (d) **Exercise 4.** Explain how AdaBoost reduces error by combining weak learners.

Solution. AdaBoost trains a sequence of weak learners on reweighted versions of the training set, focusing on previously misclassified examples. The combined hypothesis has error bounded by a product that decreases exponentially with the number of rounds, provided each weak learner has error below $1/2$.

- (e) **Exercise 5.** Why might Rademacher complexity give tighter generalisation bounds than VC dimension?

Solution. VC dimension is a worst-case measure that depends only on the hypothesis class, while Rademacher complexity depends on the specific data distribution through the supremum over random labelings. A class that looks rich in the worst case may fit random noise poorly on a particular dataset, so Rademacher-based bounds can be tighter in practice.

Chapter 22

Control theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How can a system reach a desired state despite disturbances, delay, and imperfect measurements?

Formal

Control theory designs inputs that make a dynamical system behave as desired. A controller compares a measured process variable with a reference value, uses the error as feedback, and chooses a corrective action. The design must balance speed, accuracy, stability, energy, constraints, and uncertainty.

2. History

Historical development

(a) The problem and its history.

A dynamical system changes with time. A room has a temperature, a vehicle has a position and speed, and a spacecraft has an orientation and fuel level. An input can change the

system, while disturbances such as wind, friction, noise, or an unexpected load push it away from the desired state.

The controller measures a process variable, compares it with a reference or set point, and forms the error

$$e(t) = \text{set point} - \text{measured value}.$$

It uses this error to generate a control action. A thermostat turns heating on when the measured temperature is below the target. Cruise control changes engine power when the speed differs from the set speed. The aim is not simply to act strongly; excessive correction causes overshoot or oscillation. [1, 2]

Control systems existed in mechanical form long before the modern theory. James Clerk Maxwell analyzed the stability of centrifugal governors in 1868 and explained how delay can produce self-oscillation. Edward Routh, Charles Sturm, and Adolf Hurwitz developed stability criteria. Nicolas Minorsky developed proportional-integral-derivative control for ship steering in the 1920s. Aircraft control, World War II guidance, the Space Race, robotics, and industrial automation then drove the subject forward. [3, 4]

3. Theory

Core theory

12. Open-loop and closed-loop control.

Figure 22.1: Feedback compares a desired value with a measured output and corrects the input.

An open-loop controller gives an input without using the measured result. A washing machine may run a fixed program for a fixed time.

Open-loop control is simple, but it cannot correct an unplanned disturbance.

Closed-loop control uses feedback. A sensor measures the output; the controller compares it with the target; and the actuator changes the input. Negative feedback means that the controller acts to reduce the error. A block diagram commonly shows the reference, summing point, controller, plant, sensor, and feedback path.

Feedback can stabilize an unstable process, reject disturbances, and make performance less sensitive to uncertain parameters. It can also cause trouble. A delayed or excessively strong feedback signal can make the system oscillate. Every design therefore asks whether the closed loop is stable and whether it remains stable when the model is imperfect.

13. Mathematical models and transfer functions.

A simple linear time-invariant model is

$$\dot{x} = Ax + Bu, \quad y = Cx + Du,$$

where x is the state, u is the input, and y is the measured output. With state feedback $u = -Kx$, the closed-loop equation becomes

$$\dot{x} = (A - BK)x.$$

Choosing K changes the eigenvalues of $A - BK$, which determine whether small disturbances decay or grow.

In classical control, the relation between input and output is often described by a transfer function

$$G(s) = \frac{Y(s)}{U(s)},$$

obtained from differential equations using the Laplace transform. The variable s is complex. Poles of $G(s)$ describe natural modes; zeros describe cancellations or frequencies at which the response is suppressed. A block diagram lets engineers combine components by multiplication and feedback formulas.

The model is an approximation. A motor may be linearized near one operating point, while friction, saturation, backlash, and changing loads make the actual system nonlinear. Control theory studies how much performance survives such errors. [1, 5]

14. Classical control: SISO and PID.

Classical control usually treats one input and one output, called SISO control. The design can use a step response, a root-locus plot, a Bode plot, a Nyquist plot, or a frequency-response measurement.

The proportional-integral-derivative controller is

$$u(t) = K_P e(t) + K_I \int_0^t e(\tau) d\tau + K_D \frac{de}{dt}.$$

The proportional term reacts to the present error. The integral term accumulates past error and removes steady-state offset. The derivative term anticipates the trend and can reduce overshoot, although it amplifies measurement noise. Real controllers use filters and limits because actuators cannot supply infinite force.

Design specifications include settling time, rise time, percent overshoot, steady-state error, bandwidth, and gain and phase margins. Classical controllers remain common because they are inexpensive, interpretable, and easy to tune on site, even when modern state-space methods could describe the same plant more fully. [2, 6]

15. Modern control: state space and MIMO systems.

Modern control represents all important internal variables as a state vector. This is essential when several inputs and outputs interact. A large telescope may have many mirror segments, actuators, and sensors; a nuclear reactor and a biological cell may also require multiple interacting variables.

A system is controllable if inputs can move it from the relevant initial state to a desired state in finite time. It is observable if the internal state can be reconstructed from the measured outputs. For the linear system (A, B) , controllability is tested by the rank of

$$[B \ AB \ A^2B \ \dots \ A^{n-1}B].$$

For (A, C) , observability is tested by the rank of

$$\begin{bmatrix} C \\ CA \\ CA^2 \\ \vdots \\ CA^{n-1} \end{bmatrix}.$$

Without controllability, some modes cannot be moved by the actuator. Without observability, a controller cannot know which internal mode is active.

Observers estimate hidden states from measurements. The Kalman filter combines a model with noisy data and is optimal for a standard linear-Gaussian estimation problem. Pole placement chooses feedback so that the closed-loop eigenvalues have desired locations, provided the system is controllable. [7, 8]

16. Frequency-domain and time-domain analysis.

Frequency-domain analysis replaces differential equations by algebraic relations in frequency. Laplace, Fourier, and Z transforms convert continuous or discrete time signals into functions of a complex frequency. For linear systems this simplifies convolution into multiplication and makes resonance, bandwidth, gain, phase, and stability visible in plots.

Time-domain state-space analysis keeps the state as a function of time and works naturally with multiple inputs, nonzero initial conditions, nonlinear terms, and simulations. Frequency methods are especially convenient for linear SISO design; state-space methods are more flexible for modern MIMO and nonlinear systems. Engineers often use both: a simulation checks the transient response, while a frequency plot checks robustness and margins.

17. Stability and robustness.

Stability means that disturbances do not make the system diverge. Lyapunov stability asks whether trajectories that start close remain close; asymptotic stability additionally requires them to approach the desired state. Bounded-input bounded-output stability requires every bounded input to produce a bounded output for a causal system.

For a continuous-time linear system, poles must lie in the open left half of the complex plane. For a discrete-time system, poles must lie inside the unit circle. A pole on the boundary can produce a permanent oscillation or marginal behavior. For example,

$$x[n] = 0.5^n u[n]$$

has a Z-transform with a pole at 0.5, so it decays. Replacing 0.5 by 1.5 gives a pole outside the unit circle and a growing response.

Robust control designs for uncertainty in the model. A controller should tolerate small changes in mass, delay, friction, sensor calibration, and unmodeled dynamics. H-infinity loop shaping, sliding-mode control, and structured uncertainty methods explicitly trade nominal performance for guaranteed margins. [2, 9]

18. **Linear, nonlinear, decentralized, and stochastic systems.**

Linear methods are powerful because superposition holds: the response to two inputs is the sum of the separate responses. Nonlinear systems violate this rule. Robots and aircraft contain saturation, trigonometric geometry, contact, and aerodynamic effects. Nonlinear control uses Lyapunov functions, feedback linearization, backstepping, sliding modes, trajectory linearization, and differential geometry.

In decentralized control, several controllers coordinate through communication rather than one central computer. This is useful for power networks, fleets of robots, and geographically distributed plants. The communication itself may be delayed or unreliable, creating another feedback loop.

Deterministic control assumes that the model and disturbances are known functions. Stochastic control includes random shocks. It seeks policies that optimize an expected cost or a risk-sensitive criterion. Filtering and stochastic control are central in finance, robotics, navigation, and adaptive decision-making.

19. **Main control strategies.**

Optimal control chooses an input that minimizes a cost, such as fuel, time, tracking error, or energy. Pontryagin's maximum principle gives necessary conditions, while dynamic programming leads to Bellman equations. Linear-quadratic-Gaussian control combines a quadratic cost, linear dynamics, Gaussian noise, and Kalman filtering.

Model predictive control repeatedly solves a finite-horizon optimization problem, applies the first action, measures the new state, and solves again. It can include actuator and safety constraints, which explains its importance in chemical plants, engines, and energy systems. Robust control protects against model uncertainty; adaptive control identifies parameters online and changes controller gains.

Hierarchical and networked control arrange devices and software

in levels. Intelligent control combines neural networks, Bayesian methods, fuzzy logic, evolutionary algorithms, or machine learning with a dynamic model. These methods can help with poorly known systems, but safety and stability cannot be assumed merely because a prediction is accurate on training data. [6, 10]

20. Applications and connections.

Control theory depends on differential equations, linear algebra, transforms, probability, optimization, numerical simulation, and dynamical systems. It helps robotics by turning desired motion into actuator commands, aerospace by stabilizing aircraft and spacecraft, manufacturing by keeping temperature and pressure within limits, and medicine by regulating drug delivery and artificial organs.

Feedback also appears in economics, operations research, biology, and artificial intelligence. A market model responds to prices; a population responds to resources; a learning system changes its parameters from errors. The same mathematical questions recur: what is measured, what can be changed, how fast does the correction act, and what happens when the model is wrong?

4. Important theorems and results

- (a) **Routh–Hurwitz criterion.** The coefficients of a real polynomial determine, through a finite array calculation, whether all roots lie in the open left half-plane. This gives a stability test without solving for every root. [3]
- (b) **Pole-location criterion.** A continuous-time linear transfer function is asymptotically stable when all poles have negative real part; a discrete-time system is stable when all poles lie inside the unit circle. [2]
- (c) **Controllability and observability tests.** The Kalman rank tests determine whether a finite-dimensional linear system can be driven and reconstructed from its inputs and outputs. [7]
- (d) **Separation principle.** Under standard linear assumptions, a controller designed from an estimated state and a Kalman observer can be designed in separate pieces: the feedback and observer poles combine in the closed loop. [8]

- (e) **Bellman principle.** An optimal control policy has optimal remaining decisions after every intermediate state, leading to dynamic programming and the Hamilton–Jacobi–Bellman equation. [10]

5. Applications

State-space models, feedback, and stability criteria connect measured system behavior with inputs designed to regulate it.

- (a) Aircraft and spacecraft
- (b) robots
- (c) industrial plants
- (d) vehicles
- (e) power grids
- (f) communication systems
- (g) economics
- (h) biology
- (i) artificial intelligence
- (j) and any process in which feedback changes behavior.

6. Connections

Using existing theories

- (a) Differential equations model the plant, linear algebra describes state and output maps, and complex analysis locates poles and zeros.
- (b) Optimization and probability enter when control effort, noise, uncertainty, and competing performance goals must be balanced.

Helping other theories

- (a) Control theory helps robotics, aircraft, industrial processes, power systems, and autonomous vehicles keep a desired state despite disturbances.
- (b) Its stability and observability tests also guide system identification, signal filtering, and the design of feedback in biological and economic models.

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1.** For $\dot{x} = ax$ with feedback $u = -kx$ and plant equation $\dot{x} = ax + u$, when is the closed loop asymptotically stable?

Solution. The closed loop is $\dot{x} = (a - k)x$. It decays exactly when $a - k < 0$, or $k > a$. Feedback can stabilize an unstable plant with $a > 0$ if the actuator affects the state.

- (b) **Exercise 2.** What is the purpose of the integral term in a PID controller?

Solution. It accumulates the error over time. If a constant disturbance leaves a nonzero steady-state error, the integral term keeps increasing the control action until that offset is removed, subject to actuator saturation.

- (c) **Exercise 3.** What does controllability mean in plain language?

Solution. It means that the available inputs can move the system from its current state to the desired state, at least within the model, in finite time. An unactuated mode makes the system uncontrollable.

- (d) **Exercise 4.** Why might a system be observable but not controllable?

Solution. Sensors may reveal an internal mode while actuators cannot influence it. Observation concerns what can be inferred

from outputs; controllability concerns what can be changed by inputs. They are logically different properties.

- (e) **Exercise 5.** Why can feedback destabilize a system?

Solution. If the correction is delayed, too strong, or based on a noisy measurement, the controller may overcorrect. The resulting closed-loop poles can move outside the stable region, creating growing oscillations rather than reducing the error.

Chapter 23

Deformation theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. If a mathematical object is nudged slightly, which nearby objects are genuinely different, and which changes are merely a change of coordinates?

Formal

Deformation theory studies families of solutions that vary with a small parameter. It first finds infinitesimal changes, then identifies obstructions to extending them to actual families, and finally organizes all families in moduli spaces. The same pattern applies to shapes, equations, algebras, representations, bundles, and arithmetic objects.

2. History

Historical development

- (a) The question and the historical development.

Imagine a rigid triangle, a flexible surface, or a polynomial curve whose coefficients are changed slightly. Some changes produce a genuinely new object; others are only a relabeling of the old one. Deformation theory separates these possibilities. Write a family as P_ε , where ε is small. Keeping only first-order terms means that ε^2 and higher powers are ignored. The resulting linear equations describe infinitesimal deformations. But a first-order direction may fail to extend to second order, or may extend in many different ways. The obstruction to continuing the deformation is often a cohomology class.

The ideas have roots in perturbation theory, geometry, and mechanics. Kodaira and Spencer developed a systematic theory for complex manifolds. Grothendieck recast deformations in algebraic geometry using flat maps and universal families. Gerstenhaber studied deformations of algebras, and later work connected deformation theory with Hochschild cohomology, quantum groups, and string theory. [1, 2]

3. Theory

Core theory

21. Infinitesimal changes and trivial changes.

Suppose an object is defined by equations $F(x) = 0$. A deformation changes the equations to

$$F(x) + \varepsilon G(x) + O(\varepsilon^2) = 0.$$

Substituting a moving solution and comparing coefficients of ε gives a linearized condition on G and the first-order motion of x . The solutions of this linear condition form the tangent space to the deformation problem.

Some solutions are trivial. If a coordinate change moves the original object without changing its isomorphism class, its derivative represents a direction that should be quotiented out. The true tangent space is therefore “allowed first-order changes modulo changes of coordinates.” This is why deformation theory naturally produces quotient spaces and cohomology groups.

For a plane curve, changing coefficients can smooth a singular point, move it, or leave the isomorphism class unchanged. A deformation of $y^2 = x^n$ such as

$$y^2 - x^n + \varepsilon = 0$$

replaces the singular central fiber by smoother nearby fibers. The central object and the nearby objects are different fibers of one family.

22. Flat families and universal deformations.

The most general geometric formulation is a flat map

$$f : \mathcal{X} \longrightarrow S.$$

The fiber over a point $s \in S$ is the object being studied at parameter s . Flatness is the algebraic condition that prevents components from suddenly appearing or disappearing in an uncontrolled way; it is the correct replacement for “the family changes continuously” in algebraic geometry.

A universal family $\mathfrak{X} \rightarrow B$ is a family from which every nearby deformation is obtained by pullback along a unique map from the parameter space to B . If uniqueness holds only up to an allowed equivalence, the family is versal rather than universal. Hilbert schemes and Quot schemes often supply parameter spaces, while moduli spaces identify points corresponding to isomorphic objects. [1, 3]

The universal picture explains why a deformation problem is not just one calculation. The base B records all nearby choices, singular points of B record obstructed or singular moduli behavior, and quotienting by symmetries prevents counting the same object repeatedly.

23. Complex manifolds and curves.

For a complex manifold X , the Kodaira–Spencer theory identifies first-order deformations of its complex structure with a sheaf cohomology group

$$H^1(X, \Theta_X),$$

where Θ_X is the holomorphic tangent bundle. The obstruction lies in a related degree-two group, often $H^2(X, \Theta_X)$.

For a Riemann surface, the obstruction group vanishes for dimension reasons. The Riemann sphere has no nontrivial deformations: its complex structure is isolated. A genus-one curve has a one-parameter family of complex structures. Every elliptic curve can be written as

$$y^2 = x^3 + ax + b,$$

but different pairs (a, b) can describe isomorphic curves. The invariant j records the true isomorphism class, while coefficient changes may be mere coordinate changes.

For a curve of genus $g \geq 2$, Serre duality identifies the deformation tangent space with the dual of the space of holomorphic quadratic differentials. Riemann–Roch gives dimension $3g - 3$ for the Teichmüller space of smooth curves. This is a concrete example of cohomology measuring the number of genuine shape changes. [2, 4]

24. Singularities and analytic algebras.

A germ of an analytic space near a point can be represented by a quotient

$$A = \mathbb{C}\{x_1, \dots, x_n\}/I,$$

where the braces denote convergent power series. A deformation is a flat family over a base germ whose special fiber is A . For the plane-curve singularity $y^2 - x^n = 0$, adding a parameter s gives

$$y^2 - x^n + s = 0.$$

The fiber at $s = 0$ is singular; nonzero fibers may be smooth. Such a nearby smooth fiber is a Milnor fiber.

The number and shape of deformations can be organized by a deformation functor. Instead of immediately constructing a geometric moduli space, one assigns to each local Artin algebra the set or groupoid of deformations over that algebra. Tangent vectors correspond to first-order extensions by dual numbers, and obstruction classes determine whether extensions to larger nilpotent bases exist. Schlessinger’s criteria and cotangent complexes provide general tests and controlling objects. [1, 5]

25. Applications in geometry, arithmetic, and physics.

Mori’s bend-and-break uses deformations of curves on algebraic varieties. A curve is moved through a family until it breaks into com-

ponents, reducing degree or genus and helping prove the existence of rational curves on Fano varieties.

Arithmetic deformation theory asks how a variety over $\mathbb{F}_p$ can lift to $\mathbb{Z}_p$ or to higher powers $\mathbb{Z}/p^n\mathbb{Z}$. For smooth curves, vanishing obstruction groups can allow compatible lifts through all orders, producing a formal scheme. The Serre–Tate theorem says that deformations of an abelian scheme are controlled by its p -divisible group.

Galois deformation theory starts with a representation

$$\rho : G \longrightarrow \mathrm{GL}_n(\mathbb{F}_p)$$

and asks whether it can be lifted to a representation over $\mathbb{Z}_p$ or another coefficient ring. This is central in modern number theory and in the study of modularity.

In deformation quantization, a commutative algebra of classical observables is deformed into a noncommutative algebra of quantum observables. In string theory and mathematical physics, deformations of algebras and geometric structures are organized by Hochschild cohomology and related higher operations. [6, 7]

26. What the theory depends on and where it is useful.

Deformation theory depends on calculus, linearization, algebraic geometry, sheaf cohomology, category theory, and moduli. It helps moduli theory by describing local parameter spaces, singularity theory by smoothing or classifying singular objects, and arithmetic geometry by lifting structures across rings of increasing precision.

Its fundamental warning is that an infinitesimal solution is not automatically an actual family. The first-order equations are necessary, but higher-order compatibility can fail. This is the reason obstruction groups and universal properties are as important as tangent spaces.

4. Important theorems and results

- (a) **Kodaira–Spencer principle.** First-order deformations of a complex manifold are controlled by $H^1(X, \Theta_X)$, with obstructions in a related degree-two group. [2]

- (b) **Riemann-surface dimension result.** The deformation space of a smooth genus- g curve has dimension 0 for $g = 0$, dimension 1 for $g = 1$, and $3g - 3$ for $g \geq 2$. [4]
- (c) **Flat-family principle.** Flat maps provide algebraic families whose fibers vary without uncontrolled changes in dimension or multiplicity. [1]
- (d) **Schlessinger principle.** Under suitable finiteness and lifting conditions, a deformation functor has a hull or pro-representing object that records all infinitesimal deformations. [5]
- (e) **Serre–Tate theorem.** Deformations of an abelian scheme are controlled by deformations of its associated p -divisible group. [6]

5. Applications

Infinitesimal deformations and obstruction classes determine which structures can change and which changes are only coordinate effects.

- (a) Algebraic geometry
- (b) complex geometry
- (c) singularity theory
- (d) moduli spaces
- (e) mathematical physics
- (f) representation theory
- (g) arithmetic geometry
- (h) and perturbation problems.

6. Connections

Using existing theories

- (a) Algebraic geometry supplies schemes and flat families, differential geometry supplies tangent spaces and vector fields, and cohomology records infinitesimal changes and obstructions.

- (b) Category theory packages the deformation problem as a functor and makes universal objects precise.

Helping other theories

- (a) Deformation theory helps moduli problems, algebraic geometry, representation theory, and mathematical physics distinguish genuine parameters from changes caused by a coordinate choice.
- (b) Obstruction classes tell when a first-order construction can be extended to an actual family.

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1.** What is an infinitesimal deformation?

Solution. It is a first-order change described by a parameter ε while ignoring ε^2 and higher powers. It is a tangent direction to the space of solutions, before checking whether the direction extends to a genuine family.

- (b) **Exercise 2.** Why are coordinate changes removed?

Solution. A coordinate change may move the equation or picture without changing the underlying object. Deformation theory studies new isomorphism classes, so it quotients out these trivial directions.

- (c) **Exercise 3.** What does flatness prevent in a family?

Solution. It prevents pathological jumps in the algebraic behavior of fibers, such as components suddenly appearing or disappearing. It formalizes a controlled variation of the object over the parameter space.

- (d) **Exercise 4.** What is the role of an obstruction class?

Solution. It measures why a first-order or lower-order deformation cannot be extended to the next order. If the obstruction

vanishes, an extension may exist; if not, that infinitesimal direction does not integrate.

- (e) **Exercise 5.** Why can different equations describe the same elliptic curve?

Solution. A change of coordinates can alter the coefficients a and b without changing the isomorphism class. The invariant j removes this redundancy and records the true complex structure.

Chapter 24

Dempster–Shafer theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How can several sources of incomplete or conflicting evidence be combined without pretending that ignorance is a precise probability?

Formal

Dempster–Shafer theory, also called evidence theory or the theory of belief functions, assigns support to sets of possibilities rather than only to single outcomes. It reports a lower value called belief and an upper value called plausibility. The gap between them records what the evidence has not decided.

2. History

Historical development

(a) The problem and its history.

Suppose a detector says that a signal is either red or yellow but cannot distinguish which. Ordinary probability forces us

to split the evidence between red and yellow, even if no reason for the split exists. Evidence theory keeps the statement as a set-valued piece of information. It distinguishes support for a claim from room left for the claim to be true.

Arthur Dempster introduced upper and lower probabilities in statistical inference. Glenn Shafer developed the framework into a general mathematical theory of evidence. Later work introduced the transferable belief model, theory of hints, alternative fusion operators, random-set interpretations, geometric models, and relational measures. [1, 2]

The subject is not simply probability with different notation. A probability assigns mass to individual outcomes or events with additivity. Dempster–Shafer theory assigns basic mass to subsets, allowing a source to say “one of these possibilities” without saying how the mass is divided among them.

3. Theory

Core theory

27. Frame of discernment and basic belief assignments.

Let X be the set of possible states. Its power set 2^X contains every subset, including the empty set and the whole set. A basic belief assignment is a function

$$m : 2^X \longrightarrow [0, 1]$$

with

$$m(\emptyset) = 0, \quad \sum_{A \subseteq X} m(A) = 1.$$

The sets with positive mass are called focal elements. The mass $m(A)$ supports the statement that the true state lies somewhere in A , but does not claim which member of A is true.

For $X = \{\text{alive}, \text{dead}\}$, a detector might assign mass 0.2 to alive, 0.5 to dead, and 0.3 to the whole set X . The final 0.3 represents ignorance, not an equal probability of 0.15 for each state. If later evidence distinguishes the states, that ignorance can be redistributed.

The theory also allows a random-set interpretation. Begin with an ordinary probability space of observations. A set-valued map sends each observation to the subset of states that remain possible. A hidden die whose faces 1 and 2 are indistinguishable produces the set $\{1, 2\}$ when that hidden face appears. Missing data in science, weather records, and computer vision naturally produce this type of set-valued observation. [1, 3]

28. Belief and plausibility.

For a hypothesis $A \subseteq X$, the belief is

$$\text{Bel}(A) = \sum_{B \subseteq A} m(B).$$

It counts all evidence that directly supports A or an even more specific subset. The plausibility is

$$\text{Pl}(A) = \sum_{B \cap A \neq \emptyset} m(B) = 1 - \text{Bel}(X \setminus A).$$

It counts evidence that does not contradict A . Therefore

$$\text{Bel}(A) \leq P(A) \leq \text{Pl}(A)$$

for every ordinary probability P compatible with the evidence.

Return to the cat example. With masses $m(\text{alive}) = 0.2$, $m(\text{dead}) = 0.5$, and $m(X) = 0.3$,

$$\text{Bel}(\text{alive}) = 0.2, \quad \text{Pl}(\text{alive}) = 0.2 + 0.3 = 0.5.$$

The evidence supports alive by 0.2 and leaves at most 0.5 room for alive. The interval $[0.2, 0.5]$ is more honest than a forced number when the detector cannot resolve the situation.

Belief is a lower probability and plausibility is an upper probability. For finite X , knowing all masses, all beliefs, or all plausibilities determines the other two through finite sums and inversion. For infinite X , a belief and plausibility function may exist even when no ordinary mass function on every subset is convenient. [2, 4]

29. Combining evidence.

Suppose two independent sources assign masses m_1 and m_2 . Dempster's rule forms intersections of focal sets. If B is supported by

the first source and C by the second, their common claim is $B \cap C$. The conflicting mass is

$$K = \sum_{B \cap C = \emptyset} m_1(B)m_2(C).$$

For a nonempty A , the normalized combination is

$$(m_1 \oplus m_2)(A) = \frac{1}{1 - K} \sum_{B \cap C = A} m_1(B)m_2(C).$$

The normalization discards conflict and rescales the nonempty intersections.

This rule is appropriate when the masses express compatible belief constraints from independent sources. Other situations need cumulative, cautious, proportional, or disjunctive fusion rules. The choice of rule is a modeling assumption, not a theorem that one formula is always correct.

For two friends choosing among films X, Y, Z , Alice may assign 0.99 to X and 0.01 to Y , while Bob assigns 0.99 to Z and 0.01 to Y . If the numbers mean preferences and the goal is a film both can agree to watch, the only shared preference is Y , so the normalized combination assigns it all the mass. If the sources make completely opposed claims, $K = 1$ and the rule is undefined; that is a warning that no common supported conclusion exists. [2, 5]

30. Conflict and counterintuitive examples.

Zadeh's example shows why the meaning of a mass assignment must be stated. One doctor assigns mass 0.99 to brain tumor and 0.01 to meningitis. Another assigns 0.99 to concussion and 0.01 to meningitis. Dempster's rule normalizes the small agreement on meningitis and can assign it mass one. This is counterintuitive if the numbers mean each doctor's confidence in diagnoses: both doctors considered meningitis unlikely. It may be sensible if the numbers describe constraints and the only common conclusion is meningitis, but the interpretation must be explicit.

Even low conflict can surprise. If both doctors assign large mass to brain tumor but disagree slightly about whether the alternative is meningitis or concussion, normalization can give brain tumor complete support. A model that treats belief as proof from evidence, rather than probability that a diagnosis is true, can explain some of

these outcomes. Pearl and other authors criticized interpretations that confuse probability of truth with probability of provability, while later work studied which fusion rules are justified for which tasks. [6, 7]

31. Relation to Bayesian probability.

Bayesian probability is recovered as a special case when every focal element is a singleton. Then there is no unassigned set-level ignorance, and belief and plausibility agree:

$$\text{Bel}(A) = \text{Pl}(A) = P(A).$$

If masses are assigned to sets such as red-or-green, the theory expresses information that is weaker than a probability distribution on the individual colors.

The advantage is explicit ignorance. The cost is that belief is not generally additive on disjoint sets, and some combinations can violate intuitions or decision-theoretic principles. A Bayesian approximation redistributes the mass of each focal set among its members to obtain a probability distribution. This is useful when a downstream method accepts only singleton probabilities, but it necessarily loses information about ignorance and dependence on the chosen redistribution rule. [2, 8]

32. Other uncertainty measures and geometry.

A belief function determines a credal set: the convex set of all ordinary probability distributions P satisfying

$$P(A) \geq \text{Bel}(A) \quad \text{for every } A \subseteq X.$$

The corresponding plausibility is the upper probability over this set. Thus evidence theory is a structured form of imprecise probability. Possibility measures correspond to consonant belief functions, in which the focal sets are nested. Probability boxes represent lower and upper cumulative distributions.

For a finite frame, mass and belief values can be treated as coordinates of a point in a convex belief space. The valid points form a simplex-like geometric region, with ordinary probability distributions appearing as a special face. This picture makes mixtures, constraints, and distance between evidence sources visible.

Relational measures replace the ordinary real-number order by a partial order in a bounded lattice. A measure μ assigns an ordered value to each subset of criteria, is monotone under inclusion, sends the empty set to the least element, and sends the whole set to the greatest element. This generalizes evidence combination to preferences and multi-criteria reasoning. [9]

33. Applications and dependencies.

Dempster–Shafer theory depends on sets, probability, combinatorics, convex geometry, and decision theory. It helps sensor fusion by retaining ambiguity when cameras, radar, and microphones disagree. In diagnosis, it can distinguish evidence directly supporting a disease from evidence that merely fails to rule it out. In intelligence analysis it represents reports that identify a group of possible sources but not one individual.

The theory is useful when data are incomplete, sources report constraints rather than calibrated frequencies, and preserving ignorance matters. It is dangerous when users interpret belief intervals as ordinary confidence intervals or apply Dempster’s rule to evidence with the wrong independence semantics. A responsible application states the frame, mass assignment meaning, fusion rule, conflict handling, and final decision criterion.

4. Important theorems and results

- (a) **Belief–plausibility bounds.** For every hypothesis A , $\text{Bel}(A)$ is the sum of masses contained in A , $\text{Pl}(A)$ is the sum of masses intersecting A , and every compatible probability lies between them. [2]
- (b) **Duality.** Plausibility and belief satisfy $\text{Pl}(A) = 1 - \text{Bel}(X \setminus A)$. [2]
- (c) **Bayesian special case.** If all focal elements are singletons, belief and plausibility coincide with an ordinary probability distribution. [2]
- (d) **Dempster combination rule.** Independent mass assignments combine through nonempty intersections and normalization by $1 - K$, where K is the conflicting mass. The rule is undefined when $K = 1$. [1, 5]

- (e) **Credal-set representation.** A belief function determines a convex set of compatible probability distributions, so evidence theory can be viewed as a structured lower-and-upper probability model. [9]

5. Applications

Mass assignments, belief, plausibility, and combination rules preserve both supporting evidence and unresolved ambiguity.

- (a) Sensor fusion
- (b) diagnosis
- (c) decision support
- (d) intelligence analysis
- (e) missing data
- (f) reliability engineering
- (g) possibility theory
- (h) and imprecise probability.

6. Connections

Using existing theories

- (a) Probability supplies events and conditioning, while set theory allows a mass to be assigned to a group of possible states rather than to one state.
- (b) Combinatorics computes intersections of focal sets, and decision theory is needed when belief and plausibility lead to an interval rather than one probability.

Helping other theories

- (a) Dempster–Shafer theory helps sensor fusion and diagnosis combine evidence from sources that are incomplete or partly conflicting.

- (b) Its interval output preserves uncertainty that an ordinary probability model might hide, although the combination rule must be checked when conflict is large.

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1.** Let $X = \{a, b\}$ with $m(\{a\}) = 0.3$, $m(\{b\}) = 0.2$, and $m(X) = 0.5$. Find belief and plausibility for $\{a\}$.

Solution. Belief sums masses contained in $\{a\}$, so $\text{Bel}(\{a\}) = 0.3$. Plausibility sums masses intersecting $\{a\}$, so it is $0.3 + 0.5 = 0.8$.

- (b) **Exercise 2.** Why is $m(\{a, b\}) = 0.5$ not the same as assigning probability 0.25 to each state?

Solution. The set mass says only that the state is one of a or b . It does not choose a division. Assigning 0.25 to each adds an equal-likelihood assumption that the evidence did not provide.

- (c) **Exercise 3.** What happens when two sources have conflict $K = 1$?

Solution. Every pair of focal sets has empty intersection, so the normalizing factor $1 - K$ is zero. Dempster’s normalized rule is undefined. The correct response is to inspect the model or choose a fusion rule that retains conflict.

- (d) **Exercise 4.** When does Dempster–Shafer theory reduce to Bayesian probability?

Solution. When all nonzero mass is assigned to singleton states. Then the belief and plausibility of every event are equal, and the mass function is an ordinary probability distribution.

- (e) **Exercise 5.** Why must an application specify what the mass means?

Solution. The same numerical mass can represent a belief constraint, a probability of provability, a preference, or a

sensor reliability. Dempster's normalization can be sensible for one meaning and misleading for another, especially under conflict.

Chapter 25

Dimension theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How can the size or number of independent directions of an algebraic object be measured when the object is not a simple line, plane, or vector space?

Formal

Dimension theory studies several notions of dimension and the conditions under which they agree. In commutative algebra and algebraic geometry, the main notion is Krull dimension: the maximum length of a chain of prime ideals. It measures how many layers of algebraic subspaces a ring or scheme can contain.

2. History

Historical development

- (a) **Wolfgang Krull.**

Krull defined the dimension of a commutative ring through chains of prime ideals. This algebraic definition measures how many successive layers of algebraic subspaces can occur.

(b) **Henri Lebesgue and topological dimension theorists.**

Lebesgue and later covering-dimension researchers developed ways to assign dimension to general topological spaces. These notions allow algebraic, geometric, and topological dimensions to be compared when their hypotheses overlap.

3. Theory

Core theory

34. Why dimension needs a theory.

For a vector space, dimension is the number of vectors in a basis. For a line, plane, or manifold, it is the number of independent local coordinates. Algebraic sets can be singular, reducible, or infinitely complicated, so these familiar definitions may no longer agree or may not even apply.

Dimension theory studies several questions. How long can a chain of proper algebraic subspaces be? How many independent parameters describe a family? How many equations are needed locally? How complicated is a module's resolution? For regular geometric objects these answers often coincide; for singular or non-Noetherian objects they may differ. [?, ?]

35. Krull dimension and prime chains.

Let R be a commutative ring. A prime ideal is a set of elements closed under addition and multiplication by arbitrary ring elements such that if a product ab lies in the ideal, then a or b lies in it. Prime ideals represent irreducible algebraic conditions.

The Krull dimension of R is the supremum of the lengths of chains

$$\mathfrak{p}_0 \subsetneq \mathfrak{p}_1 \subsetneq \cdots \subsetneq \mathfrak{p}_n$$

of prime ideals. The height of a prime $\mathfrak{p}$ is the dimension of the localization $R_{\mathfrak{p}}$, equivalently the maximum length of a chain ending at $\mathfrak{p}$.

For a field k , the ring k has dimension zero because its only prime ideal is (0) . The polynomial ring $k[x]$ has the chain $(0) \subsetneq (x)$ and dimension one. The ring $k[x, y]$ has

$$(0) \subsetneq (x) \subsetneq (x, y),$$

so its dimension is two. Algebraically, the plane has two independent coordinates and two layers of prime conditions.

36. Worked example: Krull dimension of $k[x, y]/(xy)$.

Consider the quotient ring $R = k[x, y]/(xy)$, which represents the union of the two coordinate axes in the affine plane. We compute its Krull dimension by finding the longest chain of prime ideals in R .

First, the prime ideals of R correspond bijectively to prime ideals of $k[x, y]$ containing (xy) , by the lattice theorem. A prime ideal $\mathfrak{p} \supseteq (xy)$ must contain x or y (since $(xy) \subseteq \mathfrak{p}$ and $\mathfrak{p}$ is prime).

Length-0 chains. The maximal ideals are candidates for the top of a chain. For instance, $(x, y) \supseteq (xy)$ in $k[x, y]$ gives a maximal ideal in R (corresponding to the origin, the intersection point of the two axes). The zero ideal (0) in R is prime since R is a domain? No— R is *not* a domain: $\bar{x} \cdot \bar{y} = 0$ in R with neither $\bar{x}$ nor $\bar{y}$ zero. So the minimal primes of R are $(\bar{x})$ and $(\bar{y})$, corresponding to the two axes.

Length-1 chains. The chain $(\bar{x}) \subsetneq (\bar{x}, \bar{y})$ has length 1 (two primes, one inclusion), as does $(\bar{y}) \subsetneq (\bar{x}, \bar{y})$. No longer chain exists: any prime strictly containing $(\bar{x}, \bar{y})$ would correspond to a prime in $k[x, y]$ strictly containing (x, y) , which is impossible since (x, y) is maximal.

Therefore $\dim R = 1$. Geometrically, each axis is a line (dimension 1), and the union of two lines meeting at a point still has dimension 1. This confirms the general principle: quotienting by one equation typically drops dimension by at most one, and here $\dim k[x, y] = 2$ is reduced to $\dim R = 1$.

37. Polynomial rings, varieties, and chains.

For a Noetherian ring R , adjoining one polynomial variable raises the dimension:

$$\dim R[x] = \dim R + 1.$$

Thus a polynomial ring in n variables over a field has dimension n . Quotients lower dimension according to the equations imposed. A hypersurface defined by one nonzero equation in affine n -space usually has dimension $n - 1$, although singularities and components require care.

The prime spectrum $\text{Spec } R$ turns the set of prime ideals into a geometric space. Inclusion of primes becomes specialization: a larger prime represents a more constrained point. Krull dimension is then the dimension of the longest chain of geometric strata. Localization focuses on a neighborhood, while quotienting by a prime restricts to a closed irreducible subspace.

For finitely generated algebras over a field, algebraic, geometric, and transcendence dimensions agree in the expected cases. The dimension of an irreducible variety is the transcendence degree of its function field over the ground field. [?, ?]

38. Noetherian rings and principal ideal bounds.

A ring is Noetherian when every ascending chain of ideals eventually stops, or equivalently when every ideal has a finite generating set. This condition makes dimension theory tractable. Polynomial rings over Noetherian rings remain Noetherian by the Hilbert basis theorem.

Krull's principal ideal theorem says that a minimal prime over a principal ideal generated by a nonzero nonunit has height at most one. More generally, a minimal prime over an ideal generated by r elements has height at most r under standard Noetherian hypotheses. This formalizes the geometric expectation that one equation cuts dimension by at most one.

A ring is catenary when saturated prime chains between two fixed primes have the same length. Catenarity ensures that dimension behaves predictably under passage between strata. Many finitely generated algebras over fields are catenary, while arbitrary non-Noetherian rings may violate familiar dimension formulas. [?, ?]

39. Regularity, singularities, and local dimension.

At a point of an algebraic variety, the local ring records functions defined near that point. A regular local ring has dimension equal to the dimension of its cotangent or tangent space. If the tangent

space is larger than the local Krull dimension, the point is singular: too many first-order directions meet there.

For example, a crossing such as $xy = 0$ has two branches meeting at the origin. The local ring has dimension one, but the tangent space has two independent directions, signaling a singularity. A smooth curve has matching dimensions and tangent directions.

Regular rings are important because many dimension notions agree there. Cohen–Macaulay and Gorenstein conditions weaken or refine regularity by controlling depth, duality, and resolutions. These properties help determine whether intersections have the expected dimension and whether algebraic invariants behave like those of a smooth space. [?]

40. Homological and module dimensions.

Krull dimension measures prime-ideal chains. Homological dimension measures how many steps are needed to resolve a module by free or projective modules. The global dimension of a ring is the supremum of projective dimensions of its modules. For a regular Noetherian ring, the global dimension agrees with the Krull dimension in important settings.

Depth measures the length of a regular sequence in a local ring. The inequality

$$\text{depth } R \leq \dim R$$

is fundamental. Equality characterizes Cohen–Macaulay local rings. Thus dimension theory connects the geometry of strata with the algebra of equations and the complexity of solving them.

For modules, dimension can also mean length, rank, or support dimension. A module supported only at finitely many points has dimension zero, while a module whose support fills a surface has dimension two. The correct notion depends on the question being asked.

41. Valuation, non-Noetherian, and noncommutative dimensions.

A valuation ring has ideals totally ordered by inclusion. Its prime spectrum is correspondingly simple, and its dimension can often be read from the chain of prime ideals. Valuation rings provide local models in algebraic geometry and number theory.

For non-Noetherian rings, ideals need not be finitely generated, chains may be very long, and polynomial dimension formulas can fail. Little is known in full generality, so the theory studies special classes such as coherent, Prüfer, or valuative domains.

Noncommutative rings do not have prime spectra with all the same geometric behavior. One can define Krull dimension-like invariants using chains of prime ideals or modules, but left and right dimensions may differ. These notions are used in representation theory and the study of operator algebras. [?]

42. What the theory depends on and where it is useful.

Dimension theory depends on rings, ideals, modules, localization, polynomial algebra, algebraic geometry, and homological algebra. It helps algebraic geometry by measuring varieties and fibers, number theory by measuring spectra of rings of integers, and singularity theory by comparing tangent and local dimensions.

It is useful whenever a problem has several possible notions of size. A theorem that equates two dimensions is valuable because it allows a geometric calculation to be replaced by an algebraic one. A mismatch is equally informative: it can reveal a singularity, a bad intersection, or a non-Noetherian pathology.

4. Important theorems and results

- (a) **Polynomial-dimension theorem.** For a Noetherian ring or valuation ring, $\dim R[x] = \dim R + 1$ under the standard hypotheses. [?]
- (b) **Hilbert basis theorem.** If R is Noetherian, then $R[x]$ is Noetherian. This is a main reason polynomial dimension can be studied inductively. [?]
- (c) **Krull principal ideal theorem.** A minimal prime over a principal ideal has height at most one; the version for r generators gives height at most r under Noetherian assumptions. [?]
- (d) **Dimension-transcendence theorem.** For a finitely generated domain over a field, the dimension equals the transcendence degree of its fraction field over the base field. [?]

- (e) **Regularity criterion.** A Noetherian local ring is regular when its Krull dimension equals the dimension of its maximal ideal modulo its square. [?]

5. Applications

Prime chains, local rings, and homological dimensions turn the informal size of an object into computable algebraic quantities.

- (a) Algebraic geometry
- (b) commutative algebra
- (c) singularities
- (d) algebraic number theory
- (e) module theory
- (f) homological algebra
- (g) and the comparison of geometric and algebraic complexity.

6. Connections

Using existing theories

- (a) Commutative algebra supplies prime ideals and chains, algebraic geometry interprets them as geometric dimension, and homological algebra supplies projective and injective dimensions.
- (b) Noetherian hypotheses are important because they prevent uncontrolled infinite chains.

Helping other theories

- (a) Dimension theory helps algebraic geometry compare varieties, helps local algebra measure singularities, and helps homological algebra predict the length of resolutions.
- (b) A dimension is useful only after its definition and category are stated; different dimensions answer different questions.

Data dimension reduction (PCA and manifold learning). In statistics and machine learning, a dataset of N observations in $\mathbb{R}^D$ is modeled as a point cloud that may lie near a lower-dimensional submanifold. Principal Component Analysis (PCA) finds the linear subspace of largest variance by computing the eigenvalues of the covariance matrix $X^T X/D$; the number of eigenvalues exceeding a threshold is the effective dimension, analogous to choosing a generating set in a vector space. When the data lie on a nonlinear manifold (e.g., Swiss roll, face images under varying illumination), intrinsic dimension, the Krull dimension of the underlying variety or the covering dimension of the manifold, governs how many parameters are needed. The manifold-learning algorithms Isomap and LLE estimate this intrinsic dimension using covering numbers or persistent homology. A result from dimension theory that is directly applicable: if data satisfy r independent polynomial equations in $\mathbb{R}^D$, then (by the dimension-transcendence theorem) the expected Krull dimension of the algebraic set is $D - r$. This guides feature selection: knowing the true dimension prevents overfitting (too many features) or information loss (too few). For instance, facial images of one person under varying pose and lighting empirically lie near a 12–15 dimensional manifold inside $\mathbb{R}^D$ (with D in the thousands), and manifold-learning methods that respect this intrinsic dimension outperform linear PCA for recognition tasks.

7. Sample Questions

Exercise reference: [?]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1.** What is the Krull dimension of $k[x]$?

Solution. The prime chain $(0) \subsetneq (x)$ has length one, and no longer chain exists. Hence $\dim k[x] = 1$.

- (b) **Exercise 2.** Give a prime chain showing that $k[x, y]$ has dimension at least two.

Solution. The ideals (0) , (x) , and (x, y) are prime and strictly nested. The chain has length two, so the dimension is at least two; the polynomial-dimension theorem shows it is exactly two.

- (c) **Exercise 3.** What does height measure?

Solution. The height of a prime ideal is the maximum number of strict prime inclusions in a chain ending at that ideal. It measures how many algebraic layers lie below the corresponding subspace.

- (d) **Exercise 4.** Why does the crossing $xy = 0$ signal a singularity at the origin?

Solution. The curve has local dimension one, but its two branches give two independent tangent directions at the origin. The tangent dimension is therefore larger than the local dimension, which is the regularity test for singularity.

- (e) **Exercise 5.** Why are Noetherian hypotheses important?

Solution. They ensure finite generation and prevent endlessly increasing chains of ideals. Without them, polynomial dimension formulas, finite-height arguments, and geometric interpretations can fail.

Chapter 26

Distribution theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How can we differentiate a sharp impulse, a jump, or another object that is not an ordinary smooth function?

Formal

Distribution theory, also called the theory of generalized functions, treats an object by how it acts on a carefully chosen smooth test function. This makes derivatives meaningful for discontinuous and singular data and gives a rigorous language for weak solutions of differential equations.

2. History

Historical development

(a) The problem and its history.

Classical calculus differentiates smooth functions. But a step function jumps, a point source is concentrated at one location,

and a wave may have a sharp front. Their ordinary derivatives either do not exist or do not capture the idealized physical behavior. Engineers nevertheless need equations for impulses, point charges, shocks, and boundaries.

Distribution theory replaces the question “what is the value at each point?” with “what is the effect on every smooth probe?” The probe is a test function. A generalized function is a continuous linear rule that takes a test function to a number. This rule can represent an ordinary function, a measure, a point mass, or a derivative of a singular object. [1, 2]

Green functions in the nineteenth century used delta-like sources before the theory was formalized. Sergei Sobolev developed related ideas in the study of hyperbolic partial differential equations in the 1930s. Laurent Schwartz created the modern theory in the 1940s and introduced the name distribution, comparing the objects with distributed electrical charge. [3, 4]

3. Theory

Core theory

43. Test functions and distributions.

Let U be an open subset of $\mathbb{R}^n$. A test function φ is infinitely differentiable and has compact support: it is zero outside some bounded closed region. The space of such functions is denoted $\mathcal{D}(U)$. A distribution is a continuous linear functional

$$T : \mathcal{D}(U) \longrightarrow \mathbb{R}$$

or to $\mathbb{C}$. Its action is written

$$\langle T, \varphi \rangle.$$

Linearity means

$$\langle T, a\varphi + b\psi \rangle = a\langle T, \varphi \rangle + b\langle T, \psi \rangle.$$

Continuity means that test functions that converge together with all derivatives produce values that also converge.

Every locally integrable function f defines a distribution:

$$\langle T_f, \varphi \rangle = \int_U f(x) \varphi(x) dx.$$

Two locally integrable functions define the same distribution exactly when they agree almost everywhere. Thus distributions include ordinary functions but are more general. A Radon measure μ also defines one by

$$\langle T_\mu, \varphi \rangle = \int_U \varphi d\mu.$$

A point mass at the origin gives the Dirac delta:

$$\langle \delta, \varphi \rangle = \varphi(0).$$

The delta is not an ordinary function, but its action is completely well-defined. [1, 5]

44. Derivatives of distributions.

The derivative is defined by moving the derivative onto the test function:

$$\langle T', \varphi \rangle = -\langle T, \varphi' \rangle.$$

This is integration by parts without a boundary term, because φ vanishes outside a compact set. If $T = T_f$ for a smooth f , this gives the ordinary derivative. The definition also gives a derivative when f has a jump or when $T = \delta$.

Let H be the Heaviside step function, equal to zero on the negative half-line and one on the positive half-line. Then

$$\langle H', \varphi \rangle = - \int_0^\infty \varphi'(x) dx = \varphi(0),$$

so $H' = \delta$. Similarly,

$$\langle \delta', \varphi \rangle = -\varphi'(0).$$

Repeated derivatives are defined in the same way. Every distribution is infinitely differentiable in this generalized sense, even when no classical derivative exists.

This is the key to weak differential equations. Instead of requiring a solution u to have all derivatives pointwise, one asks whether the equation holds after pairing with every test function. Weak solutions can exist for rough initial data and can later be shown to become smooth under additional estimates. [2, 6]

45. Operations, localization, and support.

Distributions can be added and multiplied by numbers, so they form a vector space. They can be multiplied by a smooth function g :

$$\langle gT, \varphi \rangle = \langle T, g\varphi \rangle.$$

Composition with a smooth map is possible under suitable conditions. Restricting a distribution to an open subset makes sense because test functions supported there can be used.

The support of T is the smallest closed set outside which T acts as zero. The delta has support $\{0\}$; a smooth function has support equal to the closure of the region where it is nonzero. Compact support makes many operations, including convolution, easier.

There is an important limitation. There is no product of arbitrary distributions that extends ordinary pointwise multiplication while preserving all familiar algebraic and differential rules. The product δ^2 is not automatically defined. Products can be defined for special pairs, when their singular supports do not collide, or in specialized frameworks such as Colombeau algebras. [1, 7]

46. Tempered distributions and Fourier transforms.

Ordinary distributions use compactly supported test functions. Tempered distributions use Schwartz functions: smooth functions that, together with every derivative, decrease faster than any inverse power of $|x|$. The resulting space is denoted $\mathcal{S}'(\mathbb{R}^n)$.

Tempered distributions are important because the Fourier transform maps Schwartz functions to Schwartz functions and therefore extends by duality. A constant function transforms into a delta at zero, while a delta transforms into a constant up to normalization. A periodic wave can be represented by a sum of deltas at discrete frequencies. This makes generalized functions natural for signal processing and spectral analysis.

The Fourier transform changes differentiation into multiplication:

$$\widehat{\partial_j T}(\xi) = i\xi_j \widehat{T}(\xi).$$

It changes convolution into multiplication as well. Differential equations with constant coefficients can therefore become algebraic equations in frequency, subject to the conditions needed to interpret the products. [3, 8]

47. Convolution and Green functions.

For suitable distributions T and functions or distributions S , convolution combines their effects:

$$(T * S)(x) = \int T(x - y)S(y) dy$$

when the expression makes sense. The delta is the identity for convolution, and convolving with a derivative differentiates the other factor.

A Green function is the response of a differential operator to a point source. If $LG = \delta$, then the solution of $Lu = f$ can often be written as $u = G * f$. Heat flow, electrostatics, wave propagation, and linear circuits all use this idea. The distribution framework permits the point source and the resulting singularity to be handled in one equation.

48. Distributions beyond ordinary test spaces.

Distributions may be defined on smooth manifolds by using coordinate-independent test densities. Spaces of analytic test functions lead to Sato's hyperfunctions. Analytic functions cannot have nonempty compact support, so the theory has a different structure from ordinary distributions.

Distributions with point support are finite sums of derivatives of the delta. More generally, distributions can be represented locally as derivatives of continuous functions, and tempered distributions can be treated with polynomial growth conditions. These representation results explain why the generalized objects are not arbitrary: they are controlled by ordinary functions after enough integration or differentiation. [1, 9]

49. Applications and dependencies.

Distribution theory depends on integration, linear functionals, topology, Fourier analysis, and differential equations. It helps partial differential equations by defining weak solutions, helps physics by representing point charges and impulses, and helps engineering by modeling ideal switches, shocks, and signals. It also supports Sobolev spaces, where the derivatives in a weak equation are distributions and integrability controls regularity.

In image processing, an edge is close to a derivative of a step and a point feature is close to a delta. In wave equations, a Green function

describes how a disturbance travels. In quantum mechanics, position and momentum eigenstates use delta-normalized objects that must be interpreted through test functions. The theory is useful because it lets a model keep idealized features without pretending that they are ordinary smooth graphs.

4. Important theorems and results

- (a) **Embedding theorem.** Every locally integrable function and every Radon measure defines a distribution by integration against test functions. [1]
- (b) **Distributional derivative.** The formula $\langle T', \varphi \rangle = -\langle T, \varphi' \rangle$ extends ordinary differentiation and makes the Heaviside derivative equal to the Dirac delta. [2]
- (c) **Fourier duality.** Fourier transformation extends from Schwartz functions to tempered distributions and converts differentiation into multiplication by a frequency variable. [8]
- (d) **Point-support theorem.** A distribution supported at one point is a finite linear combination of derivatives of the Dirac delta at that point. [1]
- (e) **Schwartz impossibility principle.** No multiplication of all distributions can preserve ordinary multiplication and the usual derivative rules simultaneously. Products must therefore be restricted or generalized with extra structure. [7]

5. Applications

Test functions and weak derivatives extend differentiation and integration to singular objects such as point masses and shocks.

- (a) Partial differential equations
- (b) Green functions
- (c) signal processing
- (d) wave propagation
- (e) quantum physics

- (f) image reconstruction
- (g) Fourier analysis
- (h) and engineering models with point sources or jumps.

6. Connections

Using existing theories

- (a) Real analysis supplies integration and convergence, functional analysis supplies topological vector spaces, and Fourier analysis supplies the transform of generalized functions.
- (b) Partial differential equations motivate the weak-derivative viewpoint because classical derivatives may not exist.

Helping other theories

- (a) Distribution theory helps PDEs define weak solutions, helps physics represent point sources, and helps harmonic analysis extend Fourier methods beyond ordinary functions.
- (b) It makes differentiation continuous in a larger space, so limits of smooth approximations remain usable.

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1.** What is the value of $\langle \delta, \varphi \rangle$?
Solution. It is $\varphi(0)$. The delta does not have ordinary pointwise values; it extracts the value of a test function at the origin.
- (b) **Exercise 2.** Show that the derivative of the Heaviside function is δ .

Solution. By definition,

$$\langle H', \varphi \rangle = -\langle H, \varphi' \rangle = -\int_0^\infty \varphi'(x) dx = \varphi(0),$$

because φ vanishes at infinity. This equals $\langle \delta, \varphi \rangle$.

- (c) **Exercise 3.** Why is a locally integrable function automatically a distribution?

Solution. Its integral against a compactly supported smooth function exists. Integration is linear in the test function, and convergence of the test functions with their derivatives makes the integrals converge, giving continuity.

- (d) **Exercise 4.** What does the support of a distribution mean?

Solution. It is the smallest closed set outside which the distribution acts as zero. It records where the generalized object can influence test functions.

- (e) **Exercise 5.** Why is δ^2 not automatically meaningful?

Solution. The general distribution theory defines addition, derivatives, and multiplication by smooth functions, but singularities can collide in a product. A theorem of Schwartz shows that no universal product can retain every ordinary algebraic and differential rule.

Chapter 27

Dynamical systems theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How does a state evolve through time, and what long-term behaviors can arise from a simple rule?

Formal

Dynamical systems theory studies a rule that moves a state through a state space. The rule may be a differential equation, a difference equation, a hybrid equation, or a stochastic transition. Instead of seeking an exact formula at every moment, the theory studies equilibria, periodic motion, stability, attractors, chaos, and the dependence on initial conditions.

2. History

Historical development

- (a) The central viewpoint and history.

A dynamical system has a state and a rule for updating it. The state of a pendulum may be its angle and angular velocity; the state of a lake may be the fish population and available food; the state of an economy may include prices, production, and savings. A point in the state space represents one complete snapshot. The evolution rule tells us which point comes next. Newtonian mechanics supplied the historical roots. Before fast computers, exact solutions were available only for special systems, so mathematicians developed methods for studying qualitative behavior. Modern dynamical systems theory asks questions such as whether a state settles down, whether periodic motion occurs, whether small errors grow, and whether long-term behavior depends on the starting point. [1, 2]

3. Theory

Core theory

50. Continuous, discrete, and stochastic systems.

A continuous-time system is often written

$$\dot{x} = f(x, t),$$

where $x(t)$ is a state vector. A discrete-time system uses

$$x_{n+1} = F(x_n).$$

Difference equations describe population updates, compound interest, digital filters, and iterated maps. Differential equations describe motion, chemical reactions, circuits, and fluid models.

Some systems use both kinds of time. A hybrid system may flow continuously until it hits a threshold and then jump. Equations on time scales treat continuous and discrete time within one framework. A stochastic system includes random disturbances, so the rule determines a probability distribution of future states rather than one certain trajectory.

The theory does not require the equations to arise from a least-action principle. Classical mechanics is one important source, but biological, economic, and engineered systems may be postulated directly from observations or modeling assumptions.

51. Equilibria, periodic points, and stability.

An equilibrium or fixed point is a state that does not change. For $\dot{x} = f(x)$ it satisfies $f(x) = 0$; for $x_{n+1} = F(x_n)$ it satisfies $F(x) = x$. An equilibrium is attracting if nearby states move toward it. Its basin of attraction is the set of initial states that eventually approach it.

For the logistic population model

$$\dot{x} = x(1 - x),$$

the equilibria are 0 and 1. A population between zero and one increases toward 1; a small negative perturbation is physically meaningless but reveals that the stability depends on the chosen state space.

A periodic point returns after a fixed number of steps. Periodic orbits can be attracting, repelling, or neutrally stable. Sharkovskii's theorem gives a remarkable ordering of periods for continuous maps of an interval: the existence of a period-three orbit forces the existence of periodic orbits of every positive integer period. [3]

52. Nonlinear behavior and chaos.

Figure 27.1: Iteration, stability, and parameter changes connect dynamical systems with chaos and bifurcation.

Linear systems obey superposition, so their response to a sum of inputs is the sum of the separate responses. Nonlinear systems do not. Even a low-dimensional nonlinear equation can produce several attractors, bifurcations, quasiperiodic motion, or deterministic chaos.

Chaos is not randomness in the rule. A deterministic chaotic system has a precisely defined future once the initial state is known, but

nearby initial states separate exponentially for a time. The Lorenz system, developed from a simplified atmospheric model, became a famous example. Chaos theory gives formal meanings to sensitive dependence, dense periodic orbits, and topological mixing.

53. Related mathematical viewpoints.

Arithmetic dynamics studies repeated application of polynomial or rational maps to integer, rational, algebraic, or p -adic points. Symbolic dynamics replaces a continuous state by an infinite sequence of symbols and evolves it by the shift map. It can encode complicated systems using a finite alphabet.

Topological dynamics studies qualitative asymptotic properties using open sets and continuity. Ergodic theory adds an invariant measure and asks about long-run averages. Functional analysis studies operators on spaces of functions, which provides tools for infinite-dimensional dynamics and evolution equations.

Graph dynamical systems place variables on vertices of a network and update them according to neighboring states. Projected dynamical systems constrain the motion to a feasible set and connect differential equations with optimization and equilibrium problems. System dynamics describes feedback, delays, stocks, and flows. Complex systems use dynamical models when interactions prevent a simple reduction to independent parts. [1, 4]

54. Applications beyond mechanics.

In biomechanics, movement emerges from interacting nervous, muscular, skeletal, respiratory, and perceptual subsystems. In cognitive science, dynamicists model a learner's cognitive state as a trajectory influenced by internal and environmental pressures. Concepts such as self-organization, phase transitions, and attractors have been used to discuss development, including the A-not-B error, although applications must be judged by empirical evidence rather than metaphor alone.

The dynamic approach to second-language development treats acquisition and attrition as parts of one changing system. Language behavior can be nonlinear, adaptive, feedback-sensitive, and dependent on initial conditions. Similar ideas appear in ecology, epidemiology, finance, robotics, neural networks, and climate science.

55. What the theory depends on and where it is useful.

Dynamical systems theory depends on calculus, differential and difference equations, linear algebra, topology, probability, numerical simulation, and computation. It helps chaos theory by supplying the state-space framework, helps control theory by describing plants and closed loops, helps ergodic theory by providing measure-preserving maps, and helps bifurcation theory by identifying parameter changes in long-term behavior.

Its strength is qualitative prediction when exact formulas are impossible. Its danger is overinterpreting a model: a wrong equation can have the wrong attractor, and numerical trajectories can imitate chaos because of roundoff or because the model is not valid at the scale being studied.

4. Important theorems and results

- (a) **Existence and uniqueness principle.** Under suitable regularity conditions on f , the initial-value problem $\dot{x} = f(x, t)$ has a unique local solution, making the state rule well-defined. [2]
- (b) **Linearization principle.** Near a hyperbolic equilibrium, the eigenvalues of the linearized system often determine local stability and qualitative behavior. [1]
- (c) **Sharkovskii's theorem.** For continuous interval maps, a period-three orbit implies periodic orbits of every positive period, explaining why a simple map can contain extremely rich behavior. [3]
- (d) **Poincaré–Bendixson theorem.** Under its planar hypotheses, a nonempty compact limit set containing only finitely many equilibria is restricted to equilibria, periodic orbits, and connecting orbits; genuinely chaotic attractors require more room or different structure. [1]
- (e) **Lyapunov stability method.** A scalar function that decreases along trajectories can prove stability without solving the differential equation explicitly. [5]

5. Applications

State evolution, stability, recurrence, and invariant sets describe qualitative behavior when explicit time-dependent solutions are unavailable.

- (a) Classical mechanics
- (b) planetary orbits
- (c) electronic circuits
- (d) ecology
- (e) epidemiology
- (f) economics
- (g) control
- (h) biomechanics
- (i) cognitive science
- (j) graph networks
- (k) and symbolic or topological dynamics.

6. Connections

Using existing theories

- (a) Differential equations and iteration define the evolution rule, while linear algebra studies the derivative near an equilibrium.
- (b) Topology describes invariant and recurrent sets, and probability is added when the state or forcing is random.

Helping other theories

- (a) Dynamical systems helps mechanics, climate models, ecology, epidemiology, control, and economics describe change over time.
- (b) Its stability and recurrence results separate robust qualitative behavior from predictions that depend sensitively on uncertain initial data.

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1.** Find and classify the equilibria of $\dot{x} = x(1 - x)$.

Solution. Equilibria satisfy $x(1 - x) = 0$, so $x = 0$ and $x = 1$. The derivative of the right side is $1 - 2x$. At zero it is positive, so zero is unstable; at one it is negative, so one is locally asymptotically stable.

- (b) **Exercise 2.** What is the difference between an equilibrium and a periodic orbit?

Solution. An equilibrium remains at one state forever. A periodic orbit returns to its initial state after a positive time or number of steps and generally visits several states in between.

- (c) **Exercise 3.** Why can deterministic chaos look random?

Solution. The rule contains no random choice, but small uncertainty in the initial state can grow rapidly. After enough time, the observer cannot know which nearby trajectory is the actual one, so the observed sequence appears random.

- (d) **Exercise 4.** What is an attractor basin?

Solution. It is the set of initial states whose future trajectories approach a particular attractor. If several attractors exist, their basins divide the state space and small parameter or measurement changes can alter the outcome.

- (e) **Exercise 5.** Why is simulation not a proof of long-term behavior?

Solution. A finite simulation samples one initial condition for one duration with finite precision. It can miss another attractor, a rare transition, numerical instability, or behavior beyond the model's validity. Theorems and error estimates are needed for rigorous conclusions.

Chapter 28

Elimination theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How can unwanted variables be removed from a system of equations without losing the solutions we care about?

Formal

Elimination theory develops algorithms and structural results for projecting polynomial equations onto fewer variables. Substitution, resultants, discriminants, Groebner bases, and cylindrical algebraic decomposition turn a many-variable problem into equations or logical conditions in selected variables.

2. History

Historical development

(a) **The problem and its history.**

Suppose a robot arm has joint angles x, y and its endpoint coordinates are known. The equations may contain both angles,

but we want a condition only on the endpoint. Elimination theory removes variables to produce that condition. The new equation is the shadow of the original solution set under projection.

The subject grew from the need to solve polynomial systems. Bezout's theorem bounded the number of solutions in appropriate projective settings. Gaussian elimination solved linear systems by removing variables one at a time. In the nineteenth century, Hermite and Smith normal forms handled linear Diophantine equations and finitely generated abelian groups. Resultants and discriminants supplied polynomial eliminants. [1, 2]

Francis Macaulay developed multivariate resultants and U-resultants. Elimination was central in early algebra, then was neglected when Hilbert's non-effective methods became fashionable. Computer algebra revived it: Groebner bases and cylindrical algebraic decomposition made elimination algorithmic again around the 1970s. [3]

3. Theory

Core theory

56. A simple example and the geometric meaning.

Consider

$$x + y = 3, \quad xy = 2.$$

The first equation gives $y = 3 - x$, and substitution yields

$$x(3 - x) = 2, \quad x^2 - 3x + 2 = 0.$$

The two possible values $x = 1, 2$ then give $y = 2, 1$. The variable y has been eliminated, but it can be recovered by back-substitution.

For polynomial equations $f_1(x, y) = \cdots = f_r(x, y) = 0$, the solution set is an algebraic variety in the (x, y) -plane. Projecting it onto the x -axis may create a larger set unless the eliminated coordinate can actually be recovered. An elimination polynomial gives a necessary condition, and additional checks are needed to remove extraneous roots introduced by multiplication or closure.

The algebraic object is an ideal I generated by the equations. The elimination ideal

$$I \cap k[x_1, \dots, x_r]$$

contains all polynomial consequences involving only the variables we keep. The geometric projection of the original variety is related to the zero set of this ideal, with closure issues controlled by algebraic geometry.

57. Resultants and discriminants.

For two polynomials in one eliminated variable, the resultant is a determinant built from their coefficients. It vanishes exactly when the polynomials have a common root over an algebraic closure, with multiplicities encoded in the determinant. Thus

$$\text{Res}_y(f, g) = 0$$

eliminates y from $f(x, y) = 0$ and $g(x, y) = 0$.

The discriminant of a polynomial is a special resultant between the polynomial and its derivative. It vanishes when two roots collide, so it detects repeated roots and singular parameter values. In geometry it detects when curves become tangent, intersect nontransversely, or acquire a singularity.

Resultants are effective and invariant under many changes of coordinates, but determinant size grows quickly. They can also vanish for reasons that need interpretation, such as a root at infinity in a projective compactification. [3, 4]

58. Groebner bases and elimination orders.

A Groebner basis is a special generating set for a polynomial ideal, adapted to a chosen monomial order. Buchberger's algorithm repeatedly reduces pairs of polynomials until all hidden cancellations are resolved. The computation may be expensive, but the resulting basis makes membership and elimination questions systematic.

The elimination theorem says that if a Groebner basis is computed with an order that places y above x , then the basis elements involving only x form a Groebner basis for the elimination ideal $I \cap k[x]$. In practice, a triangular basis can give equations in one variable first, then in two variables, and so on. This resembles solving by substitution but works for nonlinear systems and does not divide by a coefficient that might be zero.

For example, a computer algebra system can eliminate joint variables from robot equations, obtain a polynomial for a possible position, and then solve for the joints. The system may have complex or repeated roots, so physical constraints and numerical verification remain necessary. [1, 5]

59. Logic and quantifier elimination.

Elimination also has a logical meaning. A statement

$$\exists y [f(x, y) = 0 \text{ and } g(x, y) > 0]$$

asks whether there is a value of y satisfying conditions for a given x . Quantifier elimination replaces the statement by an equivalent condition involving only x .

Over algebraically closed fields, polynomial elimination is connected with quantifier elimination for the theory of algebraically closed fields. Over the real numbers, cylindrical algebraic decomposition partitions space into cells on which polynomial signs are constant. It can decide formulas with polynomial equalities and inequalities, though its worst-case complexity is high.

This connection explains why elimination theory matters beyond equations. It turns geometric existence questions into finite logical descriptions and supports exact analysis in computer-aided design, collision detection, and real algebraic geometry. [6]

60. What the theory depends on and where it is useful.

Elimination theory depends on polynomial rings, ideals, determinants, linear algebra, algebraic geometry, algorithms, and mathematical logic. It helps algebraic geometry by computing projections and closures, invariant theory by producing coordinate-free polynomial relations, and computer algebra by making symbolic solution procedures possible.

In CAD, elimination detects whether two surfaces intersect or become tangent. In computer vision, it removes hidden depth or calibration parameters. In robot kinematics, it produces equations for reachable positions. In solving equations, it turns many variables into a sequence of lower-dimensional problems. Its limits are computational size, extraneous solutions, multiplicities, and the distinction between algebraic closure and the real solutions required by an application.

4. Important theorems and results

- (a) **Bezout's theorem.** Under suitable projective and generic hypotheses, two plane curves of degrees m and n meet in mn points counted with multiplicity. This gives a bound and explains why multiplicity matters in elimination. [2]
- (b) **Resultant criterion.** The resultant of two univariate polynomials vanishes exactly when they have a common root over an algebraic closure. [4]
- (c) **Elimination theorem.** A Groebner basis in an elimination order contains a basis for the ideal involving only the variables retained. [1]
- (d) **Nullstellensatz connection.** Over an algebraically closed field, a polynomial system has no common solution exactly when its ideal contains 1, so elimination can produce the contradiction $1 = 0$. [5]
- (e) **Quantifier-elimination principle.** In suitable theories, formulas involving quantified variables can be replaced by equivalent formulas without quantifiers; cylindrical algebraic decomposition provides a real-algebraic algorithm for polynomial inequalities. [6]

5. Applications

Resultants, Groebner bases, and elimination orders remove variables while preserving the polynomial consequences of a system.

- (a) Solving polynomial systems
- (b) robot kinematics
- (c) computer algebra
- (d) geometric intersection
- (e) invariant theory
- (f) quantifier elimination
- (g) CAD
- (h) and exact symbolic computation.

6. Connections

Using existing theories

- (a) Linear algebra supplies elimination by row reduction, commutative algebra supplies ideals and Groebner bases, and algebraic geometry interprets elimination as projection of a solution set.
- (b) Resultants and discriminants provide compact polynomial tests for common roots and singular behavior.

Helping other theories

- (a) Elimination theory helps solve polynomial systems, robotics constraints, computer-aided design, and algebraic statistics.
- (b) It turns hidden variables into explicit conditions, but the degree and coefficient growth can make exact computation expensive.

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1.** Eliminate y from $x + y = 5$ and $x - y = 1$.
Solution. Adding the equations gives $2x = 6$, so $x = 3$. Substitution gives $y = 2$. The eliminated equation is $x - 3 = 0$.
- (b) **Exercise 2.** What does a resultant tell us?
Solution. It is a polynomial in the coefficients of two equations. Its vanishing means the equations have a common value of the variable being eliminated, usually over an algebraic closure.
- (c) **Exercise 3.** Why can elimination produce extra candidate solutions?
Solution. Multiplying equations, taking closures, or eliminating over the complex numbers can introduce values that satisfy a consequence but not the original system. Every candidate must be substituted back into the original equations and any domain constraints.

- (d) **Exercise 4.** What is the purpose of an elimination order in a Groebner-basis calculation?

Solution. It makes the chosen variables more important than the variables to be removed. The basis elements that contain only the retained variables then generate the corresponding elimination ideal.

- (e) **Exercise 5.** How is quantifier elimination related to polynomial elimination?

Solution. A quantified statement such as “there exists y satisfying polynomial conditions” describes a projection of a solution set. Elimination computes an equivalent condition in the remaining variables, so algebraic projection becomes logical removal of the quantifier.

Chapter 29

Ergodic theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. When can the average seen by one system over a long time equal the average over all possible states?

Formal

Ergodic theory studies statistical properties of deterministic dynamical systems. A measure-preserving transformation moves points without changing total measure, and an ergodic transformation has no invariant region of intermediate measure. For almost every starting point, long-time averages then agree with space averages.

2. History

Historical development

(a) **The problem and its history.**

A gas contains an enormous number of particles, so tracking every trajectory is impossible. A physicist instead measures

temperature or pressure, which are averages. Ergodic theory asks when observing one deterministic trajectory for a long time gives the same answer as sampling all states at one time. The theory is built on measure theory and deterministic dynamics. There is no random noise in the equations; the apparent randomness comes from complicated motion and limited observation. Its early motivation was statistical physics, where the ergodic hypothesis proposed that time averages and ensemble averages should agree. [1, 2]

3. Theory

Core theory

61. Measure-preserving transformations and ergodicity.

Let (X, Σ, μ) be a probability space and let $T : X \rightarrow X$ be measurable. It preserves measure if

$$\mu(T^{-1}E) = \mu(E)$$

for every measurable set E . The transformation is ergodic if every essentially invariant set has measure zero or one:

$$\mu(T^{-1}E \triangle E) = 0 \implies \mu(E) \in \{0, 1\}.$$

There is no nontrivial region that the dynamics preserves as a separate statistical world.

The oatmeal analogy is useful. A spoonful of syrup is stirred through a bowl without compressing or dilating the material. An ergodic stirring eventually spreads the syrup so thoroughly that a long observation of one small portion reflects the whole bowl. Mixing is stronger: it says that two sets become asymptotically independent. Equidistribution says that visits are distributed according to the measure.

62. Examples.

Rotation of the circle by an irrational angle,

$$T(x) = x + \theta \pmod{1},$$

is ergodic. In fact it is uniquely ergodic, minimal, and equidistributed: every orbit visits intervals in the correct proportion. If $\theta = p/q$ is rational, every orbit is periodic with period q , so an interval shorter than $1/q$ produces an invariant union with intermediate measure and the map is not ergodic.

A Bernoulli shift moves an infinite sequence of independent symbols one place to the left. It is ergodic, and Kolmogorov's zero-one law explains why tail events have probability zero or one. For torus automorphisms given by an integer matrix, ergodicity is equivalent to having no eigenvalue that is a root of unity.

Hamiltonian systems preserve phase-space volume under Liouville's theorem. A compact energy surface with a nonconstant first integral has invariant subsets of intermediate measure, so it cannot be ergodic on that surface. Completely integrable systems provide an important opposite behavior: many conserved quantities constrain trajectories to lower-dimensional tori. [2, 3]

63. Time averages, space averages, and recurrence.

For an integrable observable f , the time average along the trajectory starting at x is

$$\hat{f}(x) = \lim_{N \rightarrow \infty} \frac{1}{N} \sum_{k=0}^{N-1} f(T^k x).$$

The space average on a probability space is

$$\bar{f} = \int_X f d\mu.$$

For a general measure-preserving system these may differ. For an ergodic system they agree for almost every starting point.

Poincaré's recurrence theorem says that in a finite measure-preserving system, almost every point in a measurable set eventually returns to that set. Recurrence does not mean that the trajectory returns to the exact same point; it returns arbitrarily close or revisits a set. A smaller set has a longer typical recurrence time.

If A is measurable, the time spent in A is the average of its indicator function:

$$\lim_{N \rightarrow \infty} \frac{1}{N} \sum_{k=0}^{N-1} \mathbf{1}_A(T^k x) = \mu(A)$$

for almost every x in an ergodic probability system. The average return time to A , when finite, is proportional to $1/\mu(A)$. [1, 4]

64. The ergodic theorems.

The Birkhoff pointwise ergodic theorem states that if $f \in L^1(\mu)$ and T preserves μ , then the time average exists almost everywhere. The limit is invariant under T and has the same integral as f . If T is ergodic, the invariant limit is constant and equals $\int f d\mu$.

In probabilistic form, the Birkhoff–Khinchin theorem identifies the limit with the conditional expectation of f given the sigma-algebra of invariant sets. Ergodicity makes that sigma-algebra trivial, producing the usual expected value.

Von Neumann’s mean ergodic theorem gives convergence in Hilbert-space norm. If U is a unitary or isometric operator and P projects onto its fixed vectors, then

$$\frac{1}{N} \sum_{n=0}^{N-1} U^n x \longrightarrow Px$$

in norm. For $Uf = f \circ T$, this says that averages converge to the invariant part of the function. In L^p spaces, ergodic means converge to conditional expectation under the appropriate strong or weak operator topology. [1, 5]

65. Flows, geometry, and connected subjects.

A continuous flow is a family T_t satisfying $T_{s+t} = T_s T_t$. Ergodic flows arise from differential equations. Hopf proved ergodicity of geodesic flow on negatively curved surfaces; later work extended this to variable negative curvature and higher-dimensional manifolds.

Geodesic flows on hyperbolic manifolds connect ergodic theory with Lie groups and lattices. Horocycle flows, homogeneous flows, Anosov systems, and Ratner’s theorems study how invariant measures and orbits are classified. Harmonic analysis and representation theory provide operators whose spectra reveal mixing and decay of correlations.

Number theory uses ergodic methods for Diophantine approximation, lattice actions, and the distribution of arithmetic orbits. Markov chains and stationary stochastic processes provide probabilistic examples, even though the underlying shift dynamics can be deterministic.

66. What the theory depends on and where it is useful.

Ergodic theory depends on measure theory, probability, dynamical systems, functional analysis, operator theory, and topology. It helps statistical mechanics by justifying macroscopic averages, helps number theory by translating orbit distribution into measure statements, and helps geometry by analyzing geodesic flows.

The theory is useful when individual trajectories are too complicated but averages are meaningful. It does not say that every deterministic system is ergodic. Conserved quantities, disconnected invariant regions, and stable islands can prevent time and space averages from agreeing.

4. Important theorems and results

- (a) **Poincare recurrence theorem.** Almost every point of a finite measure-preserving system returns arbitrarily close to its initial region infinitely often. [1]
- (b) **Birkhoff pointwise ergodic theorem.** Time averages of integrable observables exist almost everywhere; in an ergodic system they equal the space average almost everywhere. [1]
- (c) **Von Neumann mean ergodic theorem.** Cesaro averages of a unitary operator converge in Hilbert norm to the orthogonal projection onto its fixed-vector space. [5]
- (d) **Birkhoff–Khinchin formulation.** The pointwise time-average limit is the conditional expectation onto the invariant sigma-algebra; ergodicity makes this sigma-algebra trivial. [2]
- (e) **Kac recurrence principle.** For a measurable set of positive measure in an ergodic probability system, the mean return time is the reciprocal of its measure, under the standard return-time convention. [4]

5. Applications

Measure-preserving dynamics and invariant averages explain when long trajectories represent the statistical behavior of the whole space.

- (a) Statistical mechanics
- (b) probability
- (c) dynamical systems
- (d) harmonic analysis
- (e) geometry
- (f) Lie groups
- (g) number theory
- (h) geodesic flows
- (i) Markov processes
- (j) and recurrence questions.

6. Connections

Using existing theories

- (a) Measure theory supplies measurable spaces and invariant measures, probability supplies random variables and expectations, and analysis supplies convergence in function spaces.
- (b) Dynamical systems provides the transformations whose long-run averages are studied.

Helping other theories

- (a) Ergodic theory helps statistical mechanics replace microscopic motion by macroscopic averages, and it helps number theory and dynamics study equidistribution.
- (b) The ergodic hypothesis is a substantive modeling or structural condition, not a synonym for randomness.

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1.** Why is an irrational rotation of the circle ergodic?

Solution. Its orbit never repeats and is equidistributed around the circle. An invariant measurable set must therefore contain almost all or almost none of the orbit, giving measure zero or one.

- (b) **Exercise 2.** What is the difference between a time average and a space average?

Solution. A time average follows one orbit and averages the observed values. A space average integrates the observable over all states using the invariant measure. Ergodic theorems state when they agree.

- (c) **Exercise 3.** What does measure preservation mean?

Solution. If a set has measure $\mu(E)$, its inverse image under the transformation has the same measure. The dynamics rearranges mass but does not create or destroy it.

- (d) **Exercise 4.** Does recurrence mean a point returns exactly to its starting position?

Solution. Usually no. It means that the orbit returns arbitrarily close or revisits a measurable neighborhood. Exact return may be impossible in a continuous state space.

- (e) **Exercise 5.** Why does a conserved quantity obstruct ergodicity?

Solution. A conserved quantity partitions the phase space into level sets. If more than one level set has positive but not full measure, each is an invariant region, contradicting ergodicity.

Chapter 30

Extremal graph theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How large or dense can a graph be when a specified pattern is forbidden?

Formal

Extremal graph theory turns a vague question about the biggest possible network into a precise optimization problem. It connects global quantities, such as vertices and edges, with local patterns, such as triangles and cliques.

2. History

Historical development

(a) **The problem and its history.**

A graph is a collection of points called vertices joined by edges. The edges may represent friendships, roads, wires, or links in a computer network. A graph can be globally dense while still avoiding a particular local shape, but only up to a limit.

Extremal graph theory asks for that limit and for the graphs that reach it. In symbols, if H is a forbidden graph, $\text{ex}(n, H)$ is the greatest number of edges in an n -vertex graph containing no copy of H [1, 2].

The subject grew from Mantel's theorem in 1907, which determined the maximum number of edges in a triangle-free graph, and Turán's theorem in 1941, which treated graphs with no clique of a fixed size. The work of Erdős and Stone then showed that, for every non-bipartite forbidden graph, the leading term of the answer is controlled by its chromatic number. Hungarian mathematicians played an especially important role in the subject [3, 4].

3. Theory

Core theory

67. A first example: avoiding triangles.

Suppose n students form a network in which an edge means that two students have worked together. We want as many collaborations as possible but do not want three students who all worked with one another. Put the students into two groups, as evenly as possible, and allow every edge between the groups but none inside a group. This is a complete bipartite graph. It contains no triangle, because a triangle would need two vertices from the same group, and those two vertices are not joined.

If the groups have a and $n - a$ students, the number of edges is $a(n - a)$. This product is largest when the groups are as equal as possible, giving

$$\text{ex}(n, K_3) = \left\lfloor \frac{n^2}{4} \right\rfloor.$$

This is Mantel's theorem. It is not just a count: it says that a network exceeding this limit must contain a triangle. In a safety or incompatibility network, that conclusion can be more useful than the construction itself.

68. Turán graphs and forbidden cliques.

The complete graph K_r has r vertices with every pair joined. Turan's theorem asks for the largest n -vertex graph with no K_{r+1} . Divide the vertices into r nearly equal groups, join every pair of vertices in different groups, and leave each group independent. The resulting Turan graph $T(n, r)$ has no $(r + 1)$ -clique and has the maximum possible number of edges. The balanced construction is forced: if one group were much larger than another, moving a vertex would increase the number of cross-group edges.

The theorem illustrates the characteristic proof pattern of extremal graph theory. First construct an example showing that a proposed bound can be reached. Then prove that every graph above the bound contains the forbidden object. The extremal graph is often highly organized rather than random.

69. Coloring as an extremal question.

A proper vertex coloring assigns colors so that adjacent vertices receive different colors. The smallest possible number of colors is the chromatic number $\chi(G)$. A clique of size $\omega(G)$ requires at least $\omega(G)$ colors. An independent set, in which no two vertices are adjacent, can contain at most $\alpha(G)$ vertices of any one color, so

$$\chi(G) \geq \frac{|V(G)|}{\alpha(G)}.$$

A greedy algorithm gives $\chi(G) \leq \Delta(G) + 1$, where $\Delta(G)$ is the largest vertex degree. Brooks' theorem improves this to $\Delta(G)$ except for complete graphs and odd cycles. Planar graphs need at most four colors by the four-color theorem [2, 5].

These inequalities convert local restrictions into global limits. For example, if every radio transmitter can interfere with at most five others, six frequencies always suffice by greedy coloring. A sharper structural theorem may show that five suffice unless the interference graph has a special form. Finding whether a general graph has a coloring with a prescribed number of colors is NP-hard, so extremal bounds are valuable even when exact computation is impractical.

Edge coloring assigns colors to edges so that edges sharing a vertex differ. Its minimum is the chromatic index $\chi'(G)$. Vizing's theorem says that every simple graph satisfies

$$\Delta(G) \leq \chi'(G) \leq \Delta(G) + 1.$$

Thus a timetable in which each edge is a job incident to a shared resource needs either Δ or $\Delta + 1$ time slots.

70. Forbidden subgraphs and asymptotic answers.

For a fixed graph H , the forbidden-subgraph problem seeks $\text{ex}(n, H)$. Turan's theorem gives an exact answer for cliques. For a general non-bipartite H , the Erdős–Stone theorem gives the leading asymptotic term:

$$\text{ex}(n, H) = \left(1 - \frac{1}{\chi(H) - 1} + o(1)\right) \binom{n}{2}.$$

Here $o(1)$ means a quantity that becomes negligible as n grows. The surprising point is that the exact shape of H matters less than its chromatic number at the largest scale. Bipartite forbidden graphs are harder: even the correct asymptotic constant is unknown for many of them. When H is complete bipartite, the question is closely related to the Zarankiewicz problem, which asks how many incidences can avoid a complete rectangular pattern.

71. Homomorphism density and graph limits.

A graph homomorphism from H to G maps vertices of H to vertices of G while preserving edges; different vertices are allowed to map to the same place. The homomorphism density $t(H, G)$ is the probability that a randomly chosen map has this property. It is a softened way to measure how strongly H occurs in G [1].

For a large dense network, sampling every subgraph is impossible. Homomorphism densities provide statistics that survive when the network grows. A graphon is a measurable function on a square that acts as a limit object for dense graphs. In this setting $t(H, G)$ becomes an integral, and inequalities such as Cauchy–Schwarz and Holder's inequality yield relations among pattern densities. Sidorenko's conjecture proposes a sharp lower bound for the density of every bipartite graph in terms of the edge density; it remains a major open problem.

72. Regularity: finding order inside a large graph.

Szemerédi's regularity lemma says that the vertices of every sufficiently large graph can be partitioned into a bounded number of parts so that most pairs of parts behave approximately like random bipartite graphs. A pair is regular when the edge density between

large subsets is close to the density between the whole parts. The lemma does not claim that the graph itself is random. It says that a complicated graph has a coarse description with controlled irregularity [4, 6].

The counting lemma uses a regular partition to estimate the number of copies of a fixed small graph. The removal lemma says that if a graph has very few copies of a pattern, then deleting a small number of edges removes all copies. These results connect extremal graph theory to additive combinatorics, property testing, and computational complexity. Strong regularity, weak Frieze–Kannan regularity, and hypergraph versions refine the same strategy.

73. Methods and neighboring theories.

The probabilistic method proves that an object exists by showing that a random object has positive probability of having the required property. Dependent random choice, container methods, and hypergraph regularity are important techniques. Ramsey theory asks when a sufficiently large structure must contain a highly organized monochromatic pattern; spectral graph theory uses eigenvalues to control edges, expansion, and forbidden configurations. Additive combinatorics studies sets with many additive relations, and complexity theory asks how hard it is to find or certify the extremal object. The Ruzsa–Szemerédi problem and Ore’s theorem are among related results [1, 6].

74. What the theory depends on and where it is useful.

The subject depends on graph theory, counting, inequalities, probability, and optimization. It helps Ramsey theory by supplying density thresholds, helps spectral graph theory by turning eigenvalue information into edge bounds, and helps additive combinatorics through regularity and removal arguments.

In network planning, an extremal bound can certify that a proposed number of links forces a forbidden conflict. In scheduling, coloring bounds give guaranteed numbers of time slots. In algorithms, regularity and graph limits compress large dense networks into a manageable model. The limitations are equally important: a sharp asymptotic estimate may not give an exact answer for practical values of n , and many bipartite forbidden-subgraph problems remain open.

4. Important theorems and results

- (a) **Mantel's theorem.** A triangle-free graph on n vertices has at most $\lfloor n^2/4 \rfloor$ edges, with equality for the balanced complete bipartite graph [3].
- (b) **Turán's theorem.** Among n -vertex graphs with no K_{r+1} , the balanced r -partite Turan graph has the most edges [3].
- (c) **Erdős–Stone theorem.** For non-bipartite H , the leading term of $\text{ex}(n, H)$ is determined by $\chi(H)$ [1].
- (d) **Szemerédi regularity lemma.** Every sufficiently large graph has a bounded regular partition, providing a random-like coarse model [4].
- (e) **Vizing's theorem.** The chromatic index of a simple graph is Δ or $\Delta + 1$ [2].

5. Applications

Forbidden-subgraph counts and density bounds identify the largest configurations compatible with a prescribed local restriction.

- (a) Network design
- (b) communication systems
- (c) scheduling
- (d) additive combinatorics
- (e) probability
- (f) and the analysis of large data networks.

6. Connections

Using existing theories

- (a) Graph theory supplies vertices, edges, subgraphs, and coloring, while combinatorics supplies counting and probabilistic constructions.

- (b) Linear algebra and analysis can also estimate eigenvalues, expansion, and pseudorandomness in large graphs.

Helping other theories

- (a) Extremal graph theory helps network design, theoretical computer science, additive combinatorics, and property testing.
- (b) Its bounds identify the largest or smallest possible configuration under a forbidden-pattern condition, which is often more useful than classifying every graph.

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1.** Why does a complete bipartite graph contain no triangle?

Solution. Every edge joins the two different parts. A triangle has three vertices, so two must lie in the same part. Those two have no edge between them, so the triangle cannot occur.

- (b) **Exercise 2.** Find the maximum number of edges in a triangle-free graph with 13 vertices.

Solution. Mantel's theorem gives $\lfloor 13^2/4 \rfloor = \lfloor 169/4 \rfloor = 42$. A complete bipartite graph with parts of sizes 6 and 7 has $6 \cdot 7 = 42$ edges, so the bound is attained.

- (c) **Exercise 3.** What does the chromatic number of a graph measure?

Solution. It is the least number of labels or colors needed so that adjacent vertices receive different labels. For a map, it is the least number of colors needed so neighboring regions have different colors.

- (d) **Exercise 4.** A simple graph has maximum degree 7. What can be said about its edge chromatic number?

Solution. Vizing's theorem gives $7 \leq \chi'(G) \leq 8$. More information about the shape of the graph is needed to decide which value occurs.

- (e) **Exercise 5.** Why is the regularity lemma useful even though it does not make a graph truly random?

Solution. It supplies a bounded coarse partition. Counts and densities of fixed small patterns can then be estimated from the parts, making a huge graph analyzable without inspecting every edge.

Chapter 31

Field theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. What is a number system in which the four basic arithmetic operations work, and how can one enlarge such a system without losing control of equations?

Formal

Field theory studies fields and their extensions. It explains why some polynomial equations can be solved by familiar numbers, why others require new numbers, and how the symmetries of the solutions reveal the answer.

2. History

Historical development

(a) **Évariste Galois.**

Galois made field extensions and their automorphism groups central to the study of polynomial equations. His correspondence between solvability by radicals and solvability of the

associated Galois group explains why some equations admit formulas and others do not.

(b) **Richard Dedekind and finite-field researchers.**

Dedekind clarified the arithmetic of field extensions through embeddings, norms, and algebraic integers. The systematic study of finite fields and extension degrees later supplied the exact arithmetic used in coding, cryptography, and algebraic number theory [1].

3. Theory

Core theory

75. What the name means.

The phrase "field theory" has several meanings. In mathematics it means the study of fields, such as the rational numbers, real numbers, complex numbers, and finite fields. In physics, field theory studies quantities spread through space and time: classical field theory, quantum field theory, and statistical field theory are related physical subjects. A grand unified theory is a proposed physical framework joining interactions. In psychology, Kurt Lewin's field theory studies the interaction of a person and environment, while sociological field theory studies social actors and local social orders. This chapter develops the mathematical meaning while keeping these other uses distinct [1, 4].

76. The basic number system.

A field is a set of numbers in which addition, subtraction, multiplication, and division by a nonzero number are always possible, and the familiar rules of arithmetic hold. The rational numbers $\mathbb{Q}$ form a field. The real numbers $\mathbb{R}$ and complex numbers $\mathbb{C}$ form larger fields. The integers do not form a field because, for example, $1/2$ is not an integer.

Finite fields also exist. The integers modulo a prime p , written $\mathbb{F}_p$, form a field because every nonzero residue has a multiplicative inverse. Modulo 5, the inverse of 2 is 3, since $2 \cdot 3 = 6$ has remainder 1. Arithmetic in finite fields is exact and bounded, which is why it is useful in digital communication and cryptography.

77. Extensions: making room for new solutions.

Figure 31.1: A field-extension lattice records how larger number systems contain one another.

If a field K is contained in a larger field L , then L/K is a field extension. The smallest field containing K and an element α is denoted $K(\alpha)$. If every element of L can be written as a combination of finitely many powers of α with coefficients in K , the extension is finite. Its degree $[L : K]$ is the number of independent coefficients required.

The equation $x^2 - 2 = 0$ has no rational solution. Adjoining $\sqrt{2}$ produces $\mathbb{Q}(\sqrt{2})$, whose elements have the form $a + b\sqrt{2}$ with $a, b \in \mathbb{Q}$. Since $(\sqrt{2})^2 = 2$, every higher power reduces to one of the first two powers, so the degree is 2. This is the controlled way in which algebra enlarges the number system.

An element α is algebraic over K if it satisfies a nonzero polynomial with coefficients in K . Among all monic polynomials that vanish at α , one of least degree is the minimal polynomial. It is irreducible over K and records all algebraic relations that α has over the base field. If no such polynomial exists, α is transcendental. The number π is an important example of a transcendental number over $\mathbb{Q}$.

78. Splitting fields and symmetries.

Given a polynomial $f(x)$ over K , its splitting field is the smallest extension in which f factors completely into linear factors. For $x^2 - 2$, the splitting field is $\mathbb{Q}(\sqrt{2})$. For $x^3 - 2$, the field must contain the real cube root of 2 and the complex cube roots, so it also contains a primitive cube root of unity.

The automorphisms of a splitting field that fix every element of K form its Galois group. An automorphism is a reversible map preserving addition and multiplication. It may permute the roots

of the polynomial, but it must preserve every algebraic relation among them. For $x^2 - 2$, the two automorphisms send $\sqrt{2}$ to $\sqrt{2}$ or $-\sqrt{2}$. The group therefore has two elements.

Galois theory creates a dictionary: intermediate fields between K and a suitable extension correspond to subgroups of the Galois group. Larger subgroups fix smaller fields, and smaller subgroups fix larger fields. The dictionary changes the problem of solving equations into the problem of understanding symmetries. It explains why general equations of degree five cannot be solved by radicals, whereas equations of degrees two, three, and four can.

79. Separable and normal extensions.

An algebraic extension is separable when every element has a minimal polynomial with distinct roots. In characteristic zero, every algebraic extension is separable. In positive characteristic, repeated roots can occur. For example, over a field of characteristic p , the polynomial $x^p - a$ has derivative zero and may have only one repeated root in a suitable extension.

An extension is normal when every irreducible polynomial over the base field that has one root in the extension splits completely there. A finite extension that is both normal and separable is Galois. The distinction matters because the clean subgroup dictionary belongs to Galois extensions, while inseparable extensions behave differently.

80. Constructing fields and understanding their size.

Every field has a characteristic. If adding 1 repeatedly eventually gives 0, the characteristic is a prime p and the field contains a copy of $\mathbb{F}_p$. Otherwise its characteristic is zero and it contains a copy of $\mathbb{Q}$. A finite field has exactly p^n elements for a prime p and positive integer n , and any two fields with the same number of elements are isomorphic. The multiplicative nonzero elements of a finite field form a cyclic group [2, 3].

Field extensions can be built by quotienting a polynomial ring by an irreducible polynomial. For example,

$$\mathbb{Q}[x]/(x^2 - 2)$$

behaves like $\mathbb{Q}(\sqrt{2})$: the class of x acts as $\sqrt{2}$, and the relation $x^2 = 2$ is imposed. Finite fields are constructed similarly from $\mathbb{F}_p[x]$ using irreducible polynomials.

81. **Geometry, number theory, and computation.**

Field theory is the algebraic foundation of algebraic geometry. Coordinates of points on a variety form a field or a ring, and extending the field describes new points that become visible after allowing new coordinates. In number theory, number fields are finite extensions of $\mathbb{Q}$; their rings of integers, ideals, places, and Galois groups encode arithmetic information.

Finite fields make arithmetic possible in computers without rounding error. Reed–Solomon codes evaluate polynomials over a finite field and recover the original message when some symbols are corrupted. Elliptic-curve cryptography uses the group of points on an elliptic curve over a finite field; the security comes from the difficulty of reversing a repeated group operation. A field is not itself a cryptosystem or code, but supplies the exact arithmetic on which these systems rely.

82. **What the theory depends on and where it is useful.**

Field theory depends on set-based algebra, polynomial arithmetic, vector spaces, and group theory. It supplies the coefficient systems used by ring theory, representation theory, algebraic geometry, number theory, coding theory, and parts of topology. Galois groups connect field theory to group theory; splitting fields connect it to polynomial equations; finite fields connect it to algorithms.

The theory also has limits. A field extension can tell us that roots exist and how they are related without producing a convenient decimal formula. A polynomial may be solvable by radicals in principle while its expression is too large to use. In positive characteristic, separability and derivative arguments require extra care.

4. Important theorems and results

(a) **Tower law.** If $K \subseteq L \subseteq M$ are finite extensions, then

$$[M : K] = [M : L][L : K].$$

It is the arithmetic rule for counting independent coefficients.

(b) **Primitive element theorem.** Many finite separable extensions can be generated by one element: $L = K(\alpha)$ [1].

- (c) **Galois correspondence.** For a finite Galois extension, intermediate fields and subgroups of the Galois group correspond in reverse order [2].
- (d) **Fundamental theorem of algebra.** Every nonconstant complex polynomial factors into linear factors over $\mathbb{C}$; thus $\mathbb{C}$ is algebraically closed.
- (e) **Finite-field theorem.** For every prime power p^n there is, up to isomorphism, exactly one field with p^n elements, and its multiplicative group is cyclic [3].

5. Applications

Field extensions, minimal polynomials, and splitting fields determine which algebraic operations are possible over a chosen number system.

- (a) Algebraic equations
- (b) finite-field arithmetic
- (c) coding
- (d) cryptography
- (e) algebraic geometry
- (f) number theory
- (g) and mathematical physics.

6. Connections

Using existing theories

- (a) Ring theory supplies polynomial quotients and ideals, linear algebra supplies extension degree, and Galois theory studies the symmetries of normal separable extensions.
- (b) Algebraic geometry and number theory provide geometric and arithmetic examples of fields.

Helping other theories

- (a) Field theory helps construct solvable equations, finite fields for coding and cryptography, and coordinate fields in algebraic geometry.
- (b) It tells us which operations preserve a problem and when adjoining a new element creates genuinely new solutions.

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1.** Why are the integers not a field?

Solution. A field requires every nonzero element to have a multiplicative inverse inside the set. The integer 2 has inverse $1/2$, which is not an integer.

- (b) **Exercise 2.** Describe an element of $\mathbb{Q}(\sqrt{2})$.

Solution. Every element is $a + b\sqrt{2}$ with rational a and b . Products reduce because $(\sqrt{2})^2 = 2$, so no higher power is needed.

- (c) **Exercise 3.** What does a minimal polynomial tell us?

Solution. It is the shortest monic polynomial over the base field that vanishes at the element. It gives the basic algebraic relation from which all other polynomial relations follow.

- (d) **Exercise 4.** How many elements does $\mathbb{F}_{2^3}$ have, and what is special about its nonzero elements?

Solution. It has $2^3 = 8$ elements. Its seven nonzero elements form a cyclic multiplicative group, so one element generates all seven by repeated multiplication.

- (e) **Exercise 5.** Why does Galois theory help solve polynomial equations?

Solution. It replaces the complicated expressions for roots by the simpler question of how symmetries permute the roots.

The subgroup structure of that symmetry group reveals which intermediate fields and radical operations are possible.

Chapter 32

Galois theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. Can the symmetries of the roots of an equation tell us whether its roots have a formula using radicals?

Formal

Galois theory connects field extensions with groups of symmetries. It replaces the difficult task of manipulating roots by the more organized task of studying the permutations that preserve every algebraic relation among them.

2. History

Historical development

(a) **The question that created the theory.**

For quadratic equations, the quadratic formula expresses the roots using addition, multiplication, division, and square roots. Cardano and Ferrari found corresponding methods for cubics

and quartics. Niels Henrik Abel proved that no formula of the same kind can solve every polynomial of degree five or more. The question then changed: which particular equations can be solved by radicals, and why? Évariste Galois supplied the answer by studying the symmetries of the roots [1, 2].

The history grew from older work on symmetric functions. The coefficients of a monic polynomial are symmetric expressions in its roots, as in $(x-a)(x-b) = x^2 - (a+b)x + ab$. Lagrange studied permutations of roots and resolvent polynomials; Ruffini and Abel established the general impossibility for the quintic; Galois identified the exact group-theoretic criterion. His memoir was published by Joseph Liouville after Galois's death and was difficult for contemporaries to understand.

3. Theory

Core theory

83. The symmetry of a quadratic.

Figure 32.1: Galois theory studies the symmetries of field extensions while fixing the base field.

Consider $x^2 - 4x + 1 = 0$. Its roots are $A = 2 + \sqrt{3}$ and $B = 2 - \sqrt{3}$. Both satisfy rational relations such as $A + B = 4$ and $AB = 1$. Swapping A and B preserves every relation whose coefficients are rational. The identity and the swap form a group of two elements. The field $\mathbb{Q}(\sqrt{3})$ contains every number obtained from rational numbers and $\sqrt{3}$ by arithmetic. An automorphism of this field that fixes $\mathbb{Q}$ may send $\sqrt{3}$ to $\sqrt{3}$ or $-\sqrt{3}$. These are exactly the two symmetries above. The Galois group is therefore the group of order two.

84. A quartic with four sign changes.

The polynomial $x^4 - 10x^2 + 1$ has roots

$$A = \sqrt{2} + \sqrt{3}, \quad B = \sqrt{2} - \sqrt{3}, \quad C = -\sqrt{2} + \sqrt{3}, \quad D = -\sqrt{2} - \sqrt{3}.$$

Changing the sign of $\sqrt{2}$, changing the sign of $\sqrt{3}$, or changing both produces four valid automorphisms. They form the Klein four-group. Relations such as $AB = -1$, $AC = 1$, and $A + D = 0$ show that the image of A determines the images of all four roots. This is the central practical idea: an allowed symmetry must preserve all relations over the base field [2].

85. The modern field-theoretic picture.

Start with a field extension L/K . The Galois group $\text{Gal}(L/K)$ consists of all automorphisms of L that leave every element of K fixed. If L is the splitting field of a polynomial over K , these automorphisms permute its roots. The modern formulation works over rational, number, finite, or local fields and also handles infinite and inseparable extensions.

For a finite Galois extension, the fundamental theorem gives a reverse-order correspondence between intermediate fields $K \subseteq E \subseteq L$ and subgroups of $\text{Gal}(L/K)$. The field fixed by a subgroup H is

$$L^H = \{x \in L : h(x) = x \text{ for every } h \in H\}.$$

Large subgroups fix small fields; small subgroups fix large fields. Normal subgroups correspond to intermediate extensions that are themselves Galois.

86. Solvability by radicals.

An equation is solvable by radicals if its roots can be formed from the coefficients using arithmetic operations and repeated extraction of n th roots. A finite group is solvable when it can be built through a chain whose successive quotients are cyclic abelian groups. Galois's theorem states that a polynomial over a field of characteristic zero is solvable by radicals precisely when its Galois group is solvable, after the usual roots of unity are included [1].

Every polynomial of degree at most four has a solvable Galois group. For the general polynomial of degree $n \geq 5$, the symmetric group S_n appears, and it contains the nonsolvable alternating group A_n .

Hence there is no universal radical formula. Particular quintics may still be solvable; the theorem is about the general equation, not every equation of that degree.

87. Classical geometry.

Compass-and-straightedge constructions correspond to field extensions whose degrees are powers of two. A cube cannot be doubled because it would require constructing $\sqrt[3]{2}$, which has degree three. A general angle cannot be trisected because the required cubic need not have a constructible solution. A regular polygon with n sides is constructible exactly when n is a product of a power of two and distinct Fermat primes. Galois theory proves the completeness of this characterization, not merely the construction of known examples [3].

88. Separable, normal, and infinite extensions.

An algebraic extension is separable when every element has a minimal polynomial with distinct roots. It is normal when every irreducible polynomial over the base field with one root in the extension splits there. A finite extension that is both normal and separable is Galois. In characteristic zero separability is automatic; in positive characteristic an equation such as $x^p - a$ can have repeated roots.

The absolute Galois group of a field K is the Galois group of an algebraic closure of K over K . This lets number theorists study all finite extensions at once. Galois theory has also been generalized to Galois connections and Grothendieck's Galois theory, which captures geometric and arithmetic coverings.

89. What the theory depends on and where it is useful.

Galois theory depends on field theory, polynomial arithmetic, permutation groups, and the theory of solvable groups. It helps algebraic number theory through absolute Galois groups, algebraic geometry through coverings, and coding theory through finite-field extensions. It gives a conceptual test even when an explicit formula would be enormous.

4. Important theorems and results

- (a) **Fundamental theorem of Galois theory.** Intermediate fields of a finite Galois extension correspond contravariantly to subgroups of its Galois group [1].
- (b) **Galois solvability criterion.** A polynomial over characteristic zero is solvable by radicals exactly when its Galois group is solvable.
- (c) **Abel–Ruffini theorem.** There is no radical formula for the general polynomial of degree at least five.
- (d) **Constructibility criterion.** A real number constructible by compass and straightedge lies in an extension of degree a power of two.
- (e) **Discriminant test.** The discriminant is zero exactly when a polynomial has a repeated root; it also gives useful information about the real and complex roots of low-degree polynomials [4].

5. Applications

Automorphism groups record how roots can be permuted, converting solvability of equations into a question about group structure.

- (a) Polynomial equations
- (b) geometric constructions
- (c) number theory
- (d) finite fields
- (e) coding
- (f) and modern algebra.

6. Connections

Using existing theories

- (a) Field theory supplies extensions and minimal polynomials, group theory supplies automorphisms and subgroup structure,

and the fundamental theorem of algebra supplies the roots being permuted.

- (b) Number theory contributes finite fields, cyclotomic fields, and arithmetic examples.

Helping other theories

- (a) Galois theory helps decide whether polynomial equations can be solved by radicals and helps construct finite fields and field extensions.
- (b) Its correspondence between subgroups and intermediate fields also transfers calculations between algebraic equations and symmetry.

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1.** What are the automorphisms of $\mathbb{Q}(\sqrt{2})$ that fix $\mathbb{Q}$?

Solution. They are the identity and the map sending $\sqrt{2}$ to $-\sqrt{2}$. Every element $a+b\sqrt{2}$ is therefore sent to either $a+b\sqrt{2}$ or $a-b\sqrt{2}$.

- (b) **Exercise 2.** Why can the cube not be doubled with compass and straightedge?

Solution. Doubling the cube requires constructing $\sqrt[3]{2}$, whose minimal polynomial is $x^3 - 2$ and has degree three. A constructible number has degree a power of two, so this number is not constructible.

- (c) **Exercise 3.** What does the Galois group remember?

Solution. It remembers all field automorphisms that fix the coefficients. These automorphisms permute the roots while preserving every algebraic relation over the coefficient field.

- (d) **Exercise 4.** Does Abel–Ruffini say that no quintic can be solved?

Solution. No. It says that no single radical formula solves every quintic. Some special quintics have solvable Galois groups and can be solved by radicals.

- (e) **Exercise 5.** Why are fields and subgroups paired in reverse order?

Solution. Adding more automorphisms imposes more equations that an element must satisfy, so the fixed field becomes smaller. Removing automorphisms imposes fewer conditions, so the fixed field becomes larger.

Chapter 33

Game theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How should a decision-maker act when the result depends on what other decision-makers do?

Formal

Game theory models strategic interaction. A game is not necessarily entertainment: it is any situation with players, choices, information, and consequences that depend on several choices at once.

2. History

Historical development

(a) The problem and its history.

Ordinary optimization asks one person to choose the best action. Strategic optimization is harder because the best action changes when another person changes theirs. Cournot analyzed competition between firms in 1838. Cardano, Pascal,

Fermat, Huygens, and Waldegrave had earlier studied games of chance. John von Neumann proved the minimax theorem for two-person zero-sum games; his work with Oskar Morgenstern developed the economics of cooperative games and expected utility. Nash later proved that every finite game has an equilibrium in mixed strategies [1, 2].

3. Theory

Core theory

90. How a game is described.

The players are the decision-makers. Each has a set of actions or strategies. A payoff records the benefit or cost of every combination of choices. In a normal-form game, a payoff matrix lists these outcomes. In an extensive-form game, a decision tree records time order, observations, and information sets.

In a zero-sum game one player's gain is exactly the other's loss. Chess between perfectly matched players is an idealized example. In a non-zero-sum game, both can gain through cooperation or both can lose. A constant-sum game is equivalent to a zero-sum game after adding a dummy account that receives the remaining payoff.

91. A small payoff matrix.

Two shops choose either a high or low price. If both choose high, each earns 4. If one chooses low while the other chooses high, the low-price shop earns 6 and the high-price shop earns 1. If both choose low, each earns 2. A shop cannot choose its best price in isolation: it must anticipate the competitor.

A strategy is dominant if it is best regardless of what the other player does. A Nash equilibrium is a collection of strategies in which no player can improve by changing alone. Equilibrium does not mean that the outcome is socially best or fair; it means only that unilateral departure is unattractive.

92. Important classifications.

In a simultaneous game, players choose without observing the current choice of others, so a matrix is natural. In a sequential

game, earlier actions affect later choices, so a decision tree is natural. Perfect information means every previous action is observed, as in chess. Imperfect information means some actions are hidden, as in poker. Complete information is different: it means that the players know the rules, possible strategies, and payoffs, even if they do not observe every move [3].

Cooperative game theory allows binding agreements and studies coalitions. A characteristic function $v(S)$ assigns the total value that a coalition S can create, with $v(\emptyset) = 0$. The core consists of allocations that no coalition can improve upon. The Shapley value divides a cooperative surplus according to average marginal contribution.

Bayesian games model incomplete information. Each player has a type, such as a firm's cost or a bidder's valuation, and beliefs about the types of others. A move by nature can represent the unknown type, turning incomplete information into imperfect information. Signaling games study how informed players communicate through actions.

93. Equilibrium and strategic reasoning.

A best response is a strategy that maximizes a player's payoff when the other strategies are fixed. Nash equilibrium requires every chosen strategy to be a best response. In sequential games, subgame-perfect equilibrium removes threats that would not be credible after a particular history. Repeated games allow reputation and punishment to support cooperation. Evolutionary games replace perfect rationality by changing frequencies of successful strategies.

Von Neumann's minimax theorem says that in a finite two-player zero-sum game, the maximum guaranteed payoff equals the minimum loss that the opponent can force, once mixed strategies are allowed. The proof uses the Brouwer fixed-point theorem. This is why randomization can be rational: it prevents the opponent from predicting a profitable response.

94. Uses outside economics.

Firms use Cournot and Bertrand models to study output and prices, and auctions use Bayesian and mechanism-design models to align private information with efficient outcomes. Governments use games for voting, bargaining, fair division, public choice, and

war negotiation. Project managers model investors, contractors, subcontractors, and governments whose decisions affect a common project.

Evolutionary game theory explains why behavior that costs one animal may spread if it benefits relatives. Hamilton's rule is $br > c$, where c is the cost, b the benefit, and r the relatedness. It models kin selection, alarm calls, food sharing, territorial conflict, and the evolution of cooperation [4].

Computer scientists use games to model interactive computation, multi-agent systems, online algorithms, auctions, peer-to-peer systems, and security. Yao's principle turns a randomized algorithm into a game between an algorithm and an adversary, producing lower bounds. Game semantics interprets logic through a contest between a verifier and a falsifier. AI uses games for reinforcement learning, autonomous agents, mechanism design, and anticipating other agents.

95. **Alternative representations.**

Different applications need different encodings. Congestion games describe costs that depend on how many users choose a resource. Graphical games record local dependence among players. Timed and continuous games include time or continuous actions. Logic-based game-description languages, Petri-net games, action-graph games, and local-effect games represent structured multi-agent interaction. These descriptions save space when a full payoff table would be enormous [5].

96. **What the theory depends on and where it is useful.**

Game theory depends on probability, optimization, linear algebra, fixed-point theorems, and decision theory. It helps economics by making competition explicit, computer science by explaining distributed decisions, biology by modeling selection, and philosophy by analyzing conventions, meaning, signaling, and social norms.

Its main limitation is modeling. Real people may not be perfectly rational, may misunderstand the rules, and may care about fairness rather than only material payoff. Experiments in the centipede, dictator, and guessing games often depart from Nash predictions. Evolutionary and bounded-rationality models address some of this, but no game model replaces careful observation [2].

4. Important theorems and results

- (a) **Minimax theorem.** Every finite two-person zero-sum game has a value when mixed strategies are allowed.
- (b) **Nash existence theorem.** Every finite game has at least one Nash equilibrium in mixed strategies [1].
- (c) **Backward induction.** In a finite perfect-information game with no chance moves, rational players can solve a subgame-perfect outcome by analyzing the final decisions first.
- (d) **Shapley value.** In a cooperative game, averaging a player's marginal contribution over all joining orders gives a fair allocation satisfying standard efficiency, symmetry, dummy-player, and additivity properties.
- (e) **Hamilton's rule.** Kin-directed behavior can be favored when its benefit weighted by relatedness exceeds its cost.

5. Applications

Payoff functions, strategies, and equilibrium conditions model how each participant's choice changes the incentives of the others.

- (a) Economics
- (b) business
- (c) politics
- (d) biology
- (e) computer science
- (f) artificial intelligence
- (g) ethics
- (h) and social science.

6. Connections

Using existing theories

- (a) Probability models mixed strategies, optimization studies best responses, and linear algebra handles finite payoff matrices.
- (b) Economics supplies utility and incentives, while algorithms and graph theory enter for large games and network interactions.

Helping other theories

- (a) Game theory helps economics, auctions, bargaining, voting, biology, and computer science analyze decisions whose outcomes depend on other decision makers.
- (b) Equilibrium is a prediction of mutual consistency, not necessarily a socially best outcome, so the solution concept must match the application.

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1.** What is the difference between a dominant strategy and a Nash equilibrium?

Solution. A dominant strategy is best against every opponent action. A Nash equilibrium is a profile in which the chosen actions are mutual best responses. An equilibrium may use strategies that are not dominant.

- (b) **Exercise 2.** Why can randomizing be useful in rock-paper-scissors?

Solution. Any predictable choice can be exploited: if rock is chosen too often, the opponent chooses paper. Choosing each move with probability one third removes a predictable advantage and is the mixed-strategy equilibrium.

- (c) **Exercise 3.** Why is a subgame-perfect equilibrium stronger than Nash equilibrium?

Solution. It requires equilibrium behavior after every possible history, not only along the path that occurs. It removes promises or threats that a player would not carry out when the time came.

- (d) **Exercise 4.** In Hamilton's rule, what does r represent?

Solution. It is the expected fraction of relevant inherited information shared by the actor and recipient. Helping a close relative has a larger r than helping an unrelated individual.

- (e) **Exercise 5.** Why might an experiment fail to match a Nash prediction?

Solution. Participants may have bounded reasoning, incomplete understanding, social preferences, or concern for fairness. The mathematical equilibrium remains a consequence of the model, but the model may not describe the experiment fully.

Chapter 34

Graph theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How can relationships among objects be represented, counted, and navigated?

Formal

Graph theory studies vertices joined by edges. It gives a language for networks in which geometry is less important than connection: who is linked to whom, which routes exist, and which patterns must occur.

2. History

Historical development

(a) The idea and its history.

In a graph, vertices represent objects and edges represent relationships. Edges may be undirected, directed, weighted, colored, or repeated. A graph of a function is a different object; this chapter concerns relational graphs. Leonhard Euler's 1736

analysis of the bridges of Königsberg is usually regarded as the beginning of graph theory. He showed that the question was not about distances but about the number of times each land region was connected to a bridge.

A walk follows edges and may repeat vertices. A trail does not repeat edges. A path does not repeat vertices. A circuit returns to its starting point, and a connected graph has a path between every pair of vertices. The degree of a vertex is the number of incident edges. A tree is a connected graph with no cycle; it has exactly one path between any two vertices and $n - 1$ edges when it has n vertices [1, 2].

3. Theory

Core theory

97. **A concrete network example.**

Suppose a delivery company has warehouses as vertices and roads as edges. A shortest-path algorithm finds the least travel distance. A spanning tree connects every warehouse with no unnecessary cycle; a minimum spanning tree does so at minimum total construction cost. If a road fails, edge connectivity tells how many failures can be tolerated. If one warehouse is a bottleneck, vertex connectivity identifies the vulnerability.

Figure 34.1: A graph represents objects, relationships, and a selected route.

The same graph supports different questions. Breadth-first search discovers all vertices at increasing distance. Depth-first search detects cycles and builds a traversal tree. Dijkstra’s algorithm finds

shortest paths with nonnegative weights, while Bellman–Ford allows negative edge weights and detects a negative cycle. A maximum-flow algorithm finds how much material can pass from a source to a sink, and the max-flow min-cut theorem says that this equals the capacity of the narrowest separating cut.

98. Important graph families.

Complete graphs join every pair of vertices. Bipartite graphs split vertices into two parts with edges only across the split; they contain no odd cycle. Planar graphs can be drawn without crossings. Trees, forests, cycles, paths, regular graphs, and directed acyclic graphs are basic families. A multigraph permits repeated edges, while a simple graph has neither loops nor repeated edges.

An Eulerian circuit uses every edge exactly once. A connected graph has one precisely when every vertex has even degree. A Hamiltonian cycle visits every vertex exactly once; no equally simple degree test characterizes all Hamiltonian graphs, and deciding whether one exists is computationally difficult. This contrast illustrates why edges and vertices create different kinds of problems.

99. Coloring and matching.

A proper vertex coloring assigns different colors to adjacent vertices. The least number is the chromatic number. Scheduling exams with a shared-student conflict graph turns coloring into a timetable problem. A matching is a set of edges with no shared endpoint. In a bipartite job-assignment graph, a matching pairs workers with tasks. Hall’s marriage theorem says that a complete matching exists exactly when every group of workers has at least as many neighboring tasks as its size.

Edge coloring assigns colors to edges so adjacent edges differ. Vizing’s theorem says that a simple graph needs either Δ or $\Delta + 1$ colors, where Δ is the maximum degree. The four-color theorem states that every planar map can be colored with at most four colors.

100. Representing and measuring graphs.

An adjacency matrix records whether each ordered pair is connected. It makes matrix multiplication useful for counting walks but uses much memory for a sparse graph. An adjacency list stores only

neighbors and is efficient for sparse networks. The incidence matrix records which vertices touch which edges.

The degree sequence lists vertex degrees. The adjacency matrix has eigenvalues that reveal expansion, connectivity, and random-walk behavior; this is the subject of spectral graph theory. A graph invariant is a quantity unchanged by relabeling vertices, such as the number of connected components, chromatic number, or degree multiset. Graph isomorphism asks whether two differently labeled graphs have the same structure.

101. Planarity, surfaces, and geometry.

Euler's formula for a connected planar graph is $V - E + F = 2$, where F counts faces including the outside face. Kuratowski's theorem characterizes nonplanar graphs through subdivisions of K_5 and $K_{3,3}$. Topological graph theory studies embeddings on surfaces, while geometric graph theory places vertices in space and uses distances or crossings.

102. Applications.

In sociology, acquaintance, influence, rumor, and collaboration graphs support social-network analysis. In biology, vertices can represent habitats and edges migration routes, allowing disease spread and conservation corridors to be studied. Molecular biology uses graphs for metabolic pathways, gene regulation, protein interactions, cell clustering, and connectomics, where neurons are vertices and synapses are edges [3].

Computer networks use routing, spanning trees, flow, and connectivity. Search engines use links and random walks to rank pages. Electrical circuits can be represented by graphs whose cycles encode independent current laws. In operations research, matching, coloring, scheduling, and flow turn practical decisions into combinatorial algorithms.

103. What the theory depends on and where it is useful.

Graph theory depends on sets, counting, algorithms, linear algebra, probability, and topology. It supports extremal and Ramsey theory by expressing forbidden patterns, supports control and network science through connectivity, and supports algebra through graph symmetries and group actions.

Its abstraction is a strength but also a limit: a graph may omit geography, time, uncertainty, capacity, or the strength of a relationship. Weighted, temporal, probabilistic, hypergraph, and multilayer models add the missing information.

4. Important theorems and results

- (a) **Handshaking lemma.** The sum of all vertex degrees equals twice the number of edges.
- (b) **Euler criterion.** A connected graph has an Euler circuit exactly when every vertex has even degree.
- (c) **Hall's theorem.** A bipartite graph has a matching covering the left part exactly when every subset of the left part has at least as many neighbors.
- (d) **Max-flow min-cut theorem.** The greatest flow from source to sink equals the capacity of a minimum cut.
- (e) **Euler's planar formula and four-color theorem.** A connected planar graph satisfies $V - E + F = 2$, and every planar graph has chromatic number at most four [1].

5. Applications

Vertices, edges, paths, and connectivity reduce network questions to finite combinatorial structures that can be counted or searched.

- (a) Roads
- (b) computer networks
- (c) social networks
- (d) biology
- (e) scheduling
- (f) search engines
- (g) electrical circuits
- (h) and algorithms.

6. Connections

Using existing theories

- (a) Set theory supplies vertices and edges, combinatorics supplies counting, and linear algebra supplies adjacency matrices and spectral information.
- (b) Algorithms turn graph definitions into practical searches, while probability studies random graphs and uncertain networks.

Helping other theories

- (a) Graph theory helps routing, scheduling, social and biological networks, circuit design, and web search.
- (b) It converts a system of pairwise relationships into paths, cuts, matchings, and flows that can guide a concrete design or diagnosis.

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1.** How many edges does a tree with 20 vertices have?

Solution. Every tree with n vertices has $n - 1$ edges, so it has 19 edges.

- (b) **Exercise 2.** Can a connected graph with exactly two odd-degree vertices have an Euler circuit?

Solution. No. An Euler circuit requires every vertex to have even degree. Such a graph may have an open Euler trail beginning at one odd vertex and ending at the other.

- (c) **Exercise 3.** What does a minimum spanning tree optimize?

Solution. It connects every vertex without cycles while minimizing the total weight of selected edges. It does not necessarily minimize the distance between every pair.

- (d) **Exercise 4.** When does a bipartite graph have a matching covering every worker?

Solution. Hall's condition must hold: every set of workers must collectively be adjacent to at least as many tasks as there are workers in that set.

- (e) **Exercise 5.** Why can an adjacency list be better than a matrix?

Solution. A sparse graph has few edges compared with all possible pairs. A list stores only existing neighbors, while a matrix stores mostly zeros.

Chapter 35

Group theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. What can be learned from studying reversible operations and the symmetries they form?

Formal

A group is a collection of reversible actions that can be composed, with an identity action and an inverse for every action. Group theory studies the common structure behind rotations, permutations, arithmetic symmetries, and transformations.

2. History

Historical development

(a) **The idea of a group.**

Imagine rotating a square around its center. Four rotations return the square to itself. Doing one rotation after another gives another rotation, doing nothing is an identity, and every rotation can be undone. These operations form a group. The

elements need not be numbers; they may be permutations, matrices, motions, or functions.

Formally, a group has a binary operation that is associative, has an identity element, and gives every element an inverse. A group is abelian if the order of composition does not matter. Rotations of a circle form an abelian group, while symmetries of a square including reflections form a non-abelian dihedral group. The language separates the nature of an object from the way it is labeled [1].

3. Theory

Core theory

104. Subgroups, cosets, and quotients.

A subgroup is a smaller collection closed under the same operation. The even integers form a subgroup of the integers under addition. A subgroup partitions a group into equal-sized left or right cosets. Lagrange's theorem follows: the order of a finite subgroup divides the order of the whole group.

If a subgroup is normal, its cosets can themselves be multiplied to form a quotient group. Normal subgroups are precisely the subgroups compatible with conjugation by every group element. A homomorphism is a structure-preserving map between groups; its kernel is normal, and the first isomorphism theorem says that the quotient by the kernel is isomorphic to the image.

105. How groups solve symmetry problems.

The symmetries of an object act on the object, producing a group action. The orbit of a point is the collection of positions reachable by the group, while the stabilizer consists of actions that leave it fixed. Orbit-stabilizer says, for a finite group,

$$|G| = |\text{Orb}(x)| |\text{Stab}(x)|.$$

This counts symmetries by counting where an object can go and how many symmetries keep it there.

Permutation groups rearrange a finite set. The symmetric group S_n contains all $n!$ permutations; the alternating group A_n contains

the even permutations. Cayley's theorem embeds every group into a permutation group, showing that permutations are a universal model for abstract groups.

106. Finite groups and their classification.

Finite groups may be described by a multiplication table, generators and relations, or a presentation. Simple groups have no nontrivial normal subgroup. They are the indivisible building blocks of finite groups, in the same way that prime numbers are building blocks of integers. The classification of finite simple groups is a vast theorem showing that every finite simple group belongs to one of several families: cyclic groups of prime order, alternating groups, groups of Lie type, or one of twenty-six sporadic groups. The proof occupies thousands of pages [2].

The Sylow theorems constrain subgroups whose order is a power of a prime. They often prove that a group of a proposed order must be abelian or must contain a normal subgroup. Semidirect products explain how one group can act on another to build a larger group.

107. Representations and characters.

A representation realizes abstract group elements as matrices acting on a vector space. Matrix multiplication then performs the group operation, so linear algebra becomes available. A representation is faithful when different group elements give different matrices. Characters record traces of representation matrices; they are constant on conjugacy classes and can determine how representations decompose.

Fourier polynomials are characters of the circle group $U(1)$ acting on periodic functions. In quantum mechanics, a state space carries a representation of a symmetry group, and conserved quantities arise from symmetry through the broader principle associated with Noether. Finite-group representations are also used to analyze molecules and crystal symmetries [3].

108. Lie groups and continuous symmetry.

A Lie group is both a group and a differentiable manifold, with smooth multiplication and inversion. Rotations in three-dimensional space form the Lie group $SO(3)$. Its tangent space at the identity is a Lie algebra, whose bracket measures the first-order failure of rotations to commute.

Lie groups are the natural framework for continuous symmetries of differential equations, geometry, and physics. Differential Galois theory studies continuous symmetries of differential equations in a role analogous to permutation groups for algebraic equations. Compact Lie groups and their representations describe rotations, angular momentum, and gauge symmetries.

109. **Combinatorial and geometric group theory.**

Combinatorial group theory studies presentations, words in generators, and the word problem: can an algorithm decide whether a given word represents the identity? Free groups have no relations beyond cancellation. Adding relations produces quotient groups and often a geometric space.

Geometric group theory studies a group through a space on which it acts. A Cayley graph records generators as labeled edges, turning algebraic multiplication into paths. Hyperbolic groups imitate negative-curvature geometry, while Bass–Serre theory studies groups acting on trees. These ideas connect group theory to topology and geometry.

110. **Applications.**

Elliptic curves over finite fields have groups of points. Their discrete logarithm problem supports public-key cryptography. Diffie–Hellman key exchange uses a finite cyclic group; braid-group and other non-abelian proposals use harder group operations, though security must be analyzed carefully. Error-correcting codes use group structure to organize words and decode them. Caesar’s cipher is a simple group operation on alphabet positions [4].

Symmetry groups classify crystal patterns, molecules, tilings, and physical laws. In topology, fundamental groups record loops and coverings. In number theory, Galois groups encode symmetries of field extensions. In algebraic geometry, algebraic groups and group schemes add a compatible group operation to a geometric object.

111. **What the theory depends on and where it is useful.**

Group theory depends on set operations, functions, relations, and increasingly on linear algebra, topology, and geometry. It helps Galois theory organize root symmetries, representation theory convert algebra to matrices, Lie theory describe continuous motion, topology

classify loops, and cryptography construct one-way computational tasks.

The classification of a group may be difficult even when its definition is short. A group model also records exact symmetry, not measurement noise or approximate symmetry; applications often require additional geometry, probability, or computation.

4. Important theorems and results

- (a) **Lagrange's theorem.** The order of a subgroup of a finite group divides the order of the group.
- (b) **Cayley's theorem.** Every group is isomorphic to a subgroup of a symmetric permutation group.
- (c) **Orbit-stabilizer theorem.** For a finite group action, group size equals orbit size times stabilizer size.
- (d) **First isomorphism theorem.** A quotient by the kernel of a homomorphism is isomorphic to its image.
- (e) **Classification of finite simple groups.** Every finite simple group belongs to the cyclic, alternating, Lie-type, or sporadic families [2].

These results move from local structure to classification. Lagrange and orbit-stabilizer give numerical tests for a finite action, Cayley realizes every group as permutations, and the isomorphism theorem explains how kernels remove information. The classification theorem is a map of the possible indivisible finite symmetries; it is not a short method for identifying an arbitrary group.

5. Applications

Composition and inverses encode symmetry operations, while subgroups and representations expose the internal structure of those symmetries.

- (a) Geometry
- (b) algebra

- (c) number theory
- (d) physics
- (e) chemistry
- (f) cryptography
- (g) coding
- (h) and the classification of finite structures.

6. Connections

Using existing theories

- (a) Set theory supplies the underlying collection and operation, while algebra studies homomorphisms, subgroups, quotients, and actions.
- (b) Geometry and number theory provide important examples, and representation theory turns abstract group elements into matrices.

Helping other theories

- (a) Group theory helps describe symmetry in geometry, chemistry, physics, coding, and algorithms.
- (b) It also organizes transformations into reusable algebraic objects, so a proof about one group action can apply to many different systems.

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1.** Why do the symmetries of a square form a group?
Solution. Composing two symmetries gives another symmetry, composition is associative, doing nothing is a symmetry, and every symmetry can be undone by its inverse.

- (b) **Exercise 2.** What does Lagrange's theorem say about a group of order 15?

Solution. The order of every subgroup must divide 15. Possible subgroup orders are 1, 3, 5, and 15.

- (c) **Exercise 3.** What is the kernel of a group homomorphism?

Solution. It is the set of elements mapped to the identity of the target group. It measures which source operations become invisible under the map and is always a normal subgroup.

- (d) **Exercise 4.** What is the difference between a group and a representation?

Solution. A group is an abstract collection of operations. A representation realizes those operations as matrices or linear transformations so that linear algebra can study them.

- (e) **Exercise 5.** Why are finite groups useful in cryptography?

Solution. Group operations can be easy to perform repeatedly, while reversing a particular operation, such as a discrete logarithm, can be difficult in a well-chosen group.

Chapter 36

Hodge theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How can differential equations choose a canonical representative for a topological hole?

Formal

Hodge theory uses a metric and the Laplacian to turn a cohomology class into a unique harmonic differential form. It links topology, geometry, analysis, and algebraic geometry.

2. History

Historical development

(a) **History and motivation.**

W. V. D. Hodge developed the theory in the 1930s while studying algebraic geometry. It built on Georges de Rham's discovery that integration of differential forms can calculate topological cohomology. Hodge wanted a higher-dimensional version of the relation between real and imaginary parts of

holomorphic differentials on a Riemann surface. His proof was repaired by Hermann Weyl and Kunihiko Kodaira [?, ?].

Topology tells us that a space may have holes, but a cohomology class usually has many differential forms representing it. Hodge theory chooses one special representative by measuring size. This is the same idea as choosing the shortest vector among many vectors that describe the same displacement.

3. Theory

Core theory

112. De Rham cohomology.

On a smooth manifold M , let $\Omega^k(M)$ be the smooth differential k -forms. Exterior differentiation gives

$$0 \longrightarrow \Omega^0(M) \xrightarrow{d} \Omega^1(M) \xrightarrow{d} \cdots \xrightarrow{d} \Omega^n(M) \longrightarrow 0,$$

and $d^2 = 0$. The k th de Rham cohomology is

$$H_{\text{dR}}^k(M) = \ker(d : \Omega^k \rightarrow \Omega^{k+1}) / \text{im}(d : \Omega^{k-1} \rightarrow \Omega^k).$$

Closed forms are those with $d\omega = 0$; exact forms are derivatives of other forms. Exact forms are treated as zero because their integrals around closed cycles vanish by Stokes' theorem.

De Rham's theorem identifies this analytic construction with singular cohomology with real coefficients:

$$H_{\text{dR}}^k(M) \cong H_{\text{sing}}^k(M; \mathbb{R}).$$

Thus differential equations can detect the same holes that a topologist sees [?].

113. Concrete illustration: Hodge theory on a torus.

The simplest closed Riemann surface is the flat torus $T^2 = \mathbb{R}^2 / \mathbb{Z}^2$ of genus 1, equipped with the metric $ds^2 = dx^2 + dy^2$ where x, y are coordinates modulo 1. The de Rham cohomology groups are $H^0 \cong \mathbb{R}$ (constants), $H^1 \cong \mathbb{R}^2$ (spanned by $[dx]$ and $[dy]$), and $H^2 \cong \mathbb{R}$ (spanned by $[dx \wedge dy]$).

The harmonic representatives are precisely the constant functions (degree 0), the constant-coefficient 1-forms $\alpha dx + \beta dy$ (degree 1), and $\gamma dx \wedge dy$ (degree 2). Every closed 1-form $\omega = f dx + g dy$ with $df = \partial f / \partial y dy = 0$ and $dg = \partial g / \partial x dx = 0$ (i.e., $\partial f / \partial y = \partial g / \partial x$) can be decomposed as $\omega = dh + \eta$ where h is a function and $\eta = \bar{f} dx + \bar{g} dy$ with constant coefficients $\bar{f} = \int_0^1 \int_0^1 f dx dy$ and $\bar{g} = \int_0^1 \int_0^1 g dx dy$. The harmonic part η is the unique representative of the cohomology class $[\omega] \in H_{\text{dR}}^1(T^2)$.

Concretely, take $\omega = (2\pi x) dy$, which is closed ($d\omega = 0$) but not exact. Its harmonic representative is the constant form $\eta = dy$ (since $\int_0^1 \int_0^1 2\pi x dx dy = 1$ for the dy -coefficient and the dx -coefficient is 0). One verifies directly: $\omega - d(2\pi xy) = 2\pi x dy - 2\pi y dx - 2\pi x dy + \dots$ —more cleanly, $\omega = \eta + d(2\pi xy - 2\pi xy)$ works after subtracting a suitable exact form. This illustrates how the flat metric on T^2 selects constant-coefficient forms as the canonical representatives, generalizing the familiar fact that on S^1 the harmonic 1-form is a constant multiple of $d\theta$.

The Hodge decomposition of the Hodge numbers is $h^{0,0} = h^{1,0} = h^{0,1} = h^{1,1} = 1$, consistent with $H^1(T^2; \mathbb{C}) = H^{1,0} \oplus H^{0,1} \cong \mathbb{C}$ and the Betti numbers $b_0 = 1$, $b_1 = 2$, $b_2 = 1$, all equal as expected for a Kähler manifold.

114. The metric, adjoint, and Laplacian.

Choose a Riemannian metric. It gives an inner product on forms, and therefore an adjoint δ to d . The Hodge Laplacian is

$$\Delta = d\delta + \delta d.$$

A form is harmonic when $\Delta\omega = 0$. On a closed Riemannian manifold, a harmonic form is both closed and coclosed. Hodge's theorem says that every real cohomology class has exactly one harmonic representative. Harmonic forms are kernels of elliptic differential operators, so the cohomology groups are finite-dimensional.

The Hodge decomposition writes every form uniquely as

$$\omega = d\alpha + \delta\beta + \gamma,$$

where γ is harmonic. The three pieces are orthogonal: an exact part, a coexact part, and the part that carries the cohomology. This generalizes the Helmholtz decomposition of a vector field into gradient, curl, and harmonic components.

115. Elliptic complexes.

The de Rham complex is one example of an elliptic complex, a chain of differential operators between vector bundles whose combined Laplacian is elliptic. Atiyah and Bott extended Hodge's theorem to this setting. The associated Green operator gives

$$\text{Id} = H + \Delta G = H + G\Delta,$$

where H projects onto harmonic sections. The cohomology of the complex is canonically the space of harmonic sections. This framework includes Dolbeault, Dirac, and other complexes [?].

116. Complex projective and Kahler manifolds.

On a complex manifold, a differential form splits into types (p, q) , counting holomorphic and antiholomorphic differentials. A compact Kahler manifold has

$$H^r(X; \mathbb{C}) = \bigoplus_{p+q=r} H^{p,q}(X).$$

The decomposition is independent of the chosen Kahler metric but depends on the complex structure, whereas ordinary cohomology depends only on the underlying topological space. The wedge product respects type:

$$H^{p,q}(X) \smile H^{p',q'}(X) \subseteq H^{p+p',q+q'}(X).$$

For a smooth projective variety, the Hodge pieces agree with coherent sheaf cohomology $H^q(X, \Omega^p)$ [?].

117. Algebraic cycles and the Hodge conjecture.

An algebraic cycle is a formal combination of subvarieties. Its cohomology class has a Hodge type constrained by its complex dimension. The Hodge conjecture proposes that certain rational cohomology classes of type (p, p) arise from algebraic cycles. It is known in special cases but remains open in general.

This explains why Hodge theory matters in algebraic geometry: it turns geometric subvarieties into cohomology classes, then asks whether the converse geometric realization is possible. Poincare duality relates a cycle's homology class to its cohomology class, and integration pairs these classes with differential forms.

118. **Physics and arithmetic.**

Maxwell's equations use differential forms and Laplacian-type operators, so harmonic forms appear naturally in mathematical physics. Hodge theory is also used in gauge theory, Yang–Mills equations, and the study of moduli spaces. Although classical Hodge theory is built over the real and complex numbers, p -adic Hodge theory provides analogous tools for arithmetic geometry and number theory [?].

119. **What the theory depends on and where it is useful.**

Hodge theory depends on differential forms, cohomology, Riemannian metrics, functional analysis, elliptic PDE, and complex geometry. It helps topology by giving computable representatives, helps algebraic geometry by splitting cohomology into types, and helps number theory through p -adic analogues.

The canonical representative depends on a metric even though the cohomology class does not. The Hodge decomposition is not available for every noncompact manifold or arbitrary complex manifold; compactness, smoothness, and ellipticity supply the required control.

4. Important theorems and results

- (a) **de Rham theorem.** Smooth differential forms compute singular cohomology with real coefficients.
- (b) **Hodge theorem.** Each real cohomology class on a closed Riemannian manifold has a unique harmonic representative [?].
- (c) **Hodge decomposition.** Every differential form splits orthogonally into exact, coexact, and harmonic parts.
- (d) **Kähler decomposition.** On a compact Kähler manifold, complex cohomology splits as the direct sum of the $H^{p,q}$ pieces.
- (e) **Hodge index theorem.** The intersection form on a compact Kähler surface has a signature constrained by its Hodge decomposition.

5. Applications

The metric Laplacian selects harmonic representatives, linking differential equations to cohomology and geometric information.

- (a) Riemannian geometry
- (b) complex projective geometry
- (c) algebraic cycles
- (d) number theory
- (e) and elliptic partial differential equations.

6. Connections

Using existing theories

- (a) Differential geometry supplies metrics, differential forms, and the Laplacian; topology supplies cohomology; and complex geometry supplies the type decomposition of forms.
- (b) Analysis provides elliptic regularity, which turns an analytic equation into finite-dimensional geometric information.

Helping other theories

- (a) Hodge theory helps classify compact manifolds, study algebraic cycles, and compare topology with complex or Kahler geometry.
- (b) Harmonic representatives make cohomology classes concrete, while the decomposition constrains which topological patterns can occur.

Maxwell's equations and the Hodge star in physics.

Maxwell's equations in vacuum on a Riemannian 3-manifold (or Minkowski 4-manifold) are naturally expressed using the Hodge star operator $*$: $\Omega^k \rightarrow \Omega^{n-k}$. The electric and magnetic fields are encoded in the Faraday 2-form $F = B_1 dy \wedge dz + B_2 dz \wedge dx + B_3 dx \wedge dy + E_1 dx \wedge dt + E_2 dy \wedge dt + E_3 dz \wedge dt$. Maxwell's equations then read $dF = 0$ and $d*F = J$ (the current 3-form).

A static magnetic field with no currents satisfies $dF = 0$ and $d*F = 0$, meaning F is a harmonic 2-form with respect to the Hodge Laplacian $\Delta = d\delta + \delta d$. On $\mathbb{R}^3$ with the flat metric, harmonic 2-forms correspond to divergence-free, curl-free vector fields, exactly the fields satisfying both the magnetostatic equations. The Hodge decomposition therefore provides a rigorous mathematical foundation for the Helmholtz decomposition of electromagnetic fields: any electromagnetic field configuration decomposes uniquely into a radiation part (harmonic), an electrostatic/magnetostatic part (exact and coexact), and a gauge component. In engineering, this decomposition underlies boundary-element methods for solving Maxwell's equations in antenna design and microwave cavity analysis, where the harmonic part captures the propagating modes and the exact/coexact parts capture near-field effects that decay rapidly.

7. Sample Questions

Exercise reference: [?]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1.** Why does $d^2 = 0$ matter?

Solution. It says every exact form is closed, so the quotient of closed forms by exact forms is well-defined. Without this cancellation, there would be no cohomology group.

- (b) **Exercise 2.** What does harmonic mean for a differential form?

Solution. It means the Hodge Laplacian satisfies $\Delta\omega = 0$. On a closed manifold this implies that the form is both closed and coclosed.

- (c) **Exercise 3.** Why is the harmonic representative called canonical?

Solution. Once a metric is chosen, each cohomology class has exactly one harmonic form representing it. There is no further choice among representatives.

- (d) **Exercise 4.** What is the purpose of the decomposition $\omega = d\alpha + \delta\beta + \gamma$?

Solution. It separates a form into a derivative part, a codifferential part, and a harmonic part. Only the harmonic part survives as the essential cohomology information.

- (e) **Exercise 5.** Why does Hodge theory not apply identically to every complex manifold?

Solution. The (p, q) splitting and its good behavior require strong compatibility between the metric and complex structure, as in the Kahler condition. General complex manifolds need not have this decomposition.

Chapter 37

Homology theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How can a space's holes be turned into algebraic objects that can be calculated?

Formal

Homology replaces geometric pieces by a chain complex. Cycles are closed pieces, boundaries are pieces that bound something, and homology records cycles that are not boundaries.

2. History

Historical development

(a) **History and the central idea.**

Homology grew from Euler's polyhedron formula, Riemann's genus, and Betti's numerical invariants. It became a systematic part of algebraic topology when mathematicians learned to associate algebraic groups with spaces. The word is also used

more generally for the homology of any chain complex and for the collection of procedures called homology theories [1].

Think of a triangulated surface. A vertex is a zero-dimensional piece, an edge is a one-dimensional piece, and a triangle is a two-dimensional piece. A collection of edges can form a closed loop. If the loop is the boundary of a collection of triangles, it is not a genuine hole. If it cannot be filled, it represents a one-dimensional hole.

3. Theory

Core theory

120. Chains, cycles, and boundaries.

A chain complex is a sequence of abelian groups or modules

$$\cdots \longrightarrow C_{n+1} \xrightarrow{\partial_{n+1}} C_n \xrightarrow{\partial_n} C_{n-1} \longrightarrow \cdots$$

with $\partial_n \partial_{n+1} = 0$. The boundary of a boundary is empty. The n -cycles are $Z_n = \ker \partial_n$, and the n -boundaries are $B_n = \operatorname{im} \partial_{n+1}$. Since every boundary is a cycle, the n th homology group is

$$H_n = \frac{Z_n}{B_n}.$$

It identifies cycles that differ by a boundary.

For a connected space, H_0 is usually $\mathbb{Z}$, one copy for each connected component. H_1 records loops, and higher groups record higher-dimensional voids. The rank of a homology group is a Betti number; finite pieces such as $\mathbb{Z}_2$ are torsion.

121. Examples that build intuition.

The sphere has no one-dimensional hole, so $H_1(S^2) = 0$, but it has a two-dimensional surface class, so $H_2(S^2) = \mathbb{Z}$. A circle has one loop and no filled two-dimensional region: $H_0(S^1) = \mathbb{Z}$, $H_1(S^1) = \mathbb{Z}$, and higher homology is zero.

The torus has two independent one-dimensional loops, one around the tube and one through the hole, and one two-dimensional surface class. Its Betti numbers are 1, 2, 1. The projective plane has

$H_1 = \mathbb{Z}_2$: its essential loop becomes a boundary when traversed twice. This is torsion, a phenomenon not visible from ordinary real-valued measurements [2].

122. Simplicial and singular homology.

In simplicial homology, a space is decomposed into vertices, edges, triangles, and higher simplices. Boundary matrices make the calculation finite and algorithmic. Singular homology instead allows every continuous map from a standard simplex into the space. It works for arbitrary topological spaces and is invariant under homotopy.

Cellular homology uses cells in a CW complex and is often smaller than singular homology while producing the same answer. Cubical homology uses squares and cubes, which is useful for images and voxel data. Relative homology $H_n(X, A)$ studies chains in X modulo chains already contained in a subspace A .

123. Maps, exact sequences, and products.

A continuous map induces homomorphisms on homology. Homotopic maps induce the same homomorphism, so homology ignores continuous deformation. A pair $A \subseteq X$ gives a long exact sequence linking $H_n(A)$, $H_n(X)$, and relative homology. Mayer–Vietoris calculates a space by splitting it into overlapping pieces.

The cross product combines classes in two spaces, and the Kunneth theorem describes the homology of a product. Poincare duality relates homology and cohomology of an oriented closed manifold. The Euler characteristic is the alternating sum $\chi = \sum (-1)^n \text{rank } H_n$ and is independent of the chosen triangulation.

124. Homology theories.

Different constructions share the same formal behavior: homotopy invariance, exact sequences, excision, and a dimension rule. Singular, simplicial, cellular, de Rham, and Borel–Moore homology are examples. Generalized theories such as K-theory and cobordism homology relax the ordinary dimension rule and reveal finer structure.

In algebraic geometry, sheaf and coherent homology measure the failure of local data to fit globally. In computational topology,

persistent homology studies how homology changes as a scale parameter grows, producing a barcode that identifies robust features in noisy data [3].

125. Computation and applications.

For a finite mesh, boundary operators are matrices. Row reduction computes ranks and null spaces, while specialized algorithms preserve sparsity. Finite-element software uses homology and cohomology bases to represent fields on meshes. In data analysis, point clouds sampled from a shape are connected at a chosen distance; homology detects components, loops, and voids as the distance changes.

Homology does not reconstruct every detail of a space. Two spaces can have identical homology groups but different fundamental groups or geometry. It is a robust summary, not a complete photograph.

126. What the theory depends on and where it is useful.

Homology depends on linear algebra, abelian groups, chain complexes, and topology. It helps homotopy theory by providing computable invariants, helps geometry through Euler characteristics and duality, and helps data science by converting shape into persistence diagrams.

4. Important theorems and results

- (a) **Homotopy invariance.** Homotopic maps induce the same map on homology.
- (b) **Mayer–Vietoris sequence.** The homology of a union can be computed from the homology of two pieces and their intersection.
- (c) **Excision.** Under suitable inclusion conditions, removing a region from a pair does not change relative homology.
- (d) **Kunneth theorem.** It describes the homology of a product from the homology of its factors, including possible tensor and torsion terms.

- (e) **Poincare duality.** Homology and cohomology groups of an oriented closed manifold are paired in complementary dimensions [4].

127. Applications.

- (a) **Topological data analysis and persistent homology.** Persistent homology applies homology to finite point clouds sampled from unknown shapes. The data are embedded in $\mathbb{R}^d$, and a filtration of simplicial complexes is built by growing balls of radius ϵ around each point. As ϵ increases, new connected components appear and merge, new loops form and get filled in, and voids open and close. A persistence diagram or barcode records the birth and death parameter values for each topological feature. Long-lived bars correspond to robust structural features of the underlying space, while short bars are attributed to sampling noise. This pipeline has been applied to reconstruct the shape of proteins from molecular dynamics simulations, to detect loop structures in neuronal connectivity networks, and to identify clustering structure in high-dimensional gene-expression data. The stability theorem for persistence diagrams guarantees that small perturbations of the input point cloud produce only small displacements of the diagram in the bottleneck metric, giving the method robustness that purely algebraic invariants lack [3].
- (b) **Sensor networks and coverage analysis.** In a wireless sensor network, each sensor monitors a region modeled as a disk. The union of covered disks forms a topological space, and its homology groups determine whether the network has coverage gaps (one-dimensional holes) or redundant overlaps (higher-dimensional voids). When sensors have unknown locations, pairwise distance measurements construct a Čech or Rips complex whose homology is computed from boundary matrices. A one-dimensional homology class that persists across a range of distance scales signals a genuine hole in coverage that must be plugged, while the appearance and disappearance of classes at a single scale indicates a transient measurement error. This homology-based approach has been implemented in marine sensor arrays for ocean temperature monitoring, where persistent H_1 classes identify regions with insufficient acoustic

coverage, and in agricultural IoT networks, where H_2 classes detect three-dimensional voids in soil-moisture sensing grids [3, 4].

6. Connections

Using existing theories

- (a) Topology supplies spaces and continuous maps, while linear algebra turns chains into boundary matrices and homology groups into kernels modulo images.
- (b) Category theory explains functoriality, and algebraic geometry and differential geometry provide rich examples.

Helping other theories

- (a) Homology helps distinguish spaces, compute holes, and prove fixed-point and duality results.
- (b) It also supplies computable invariants for geometry and topology, making qualitative features accessible through finite calculations in many examples.

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1.** What does $H_0(X)$ count for a space with three path components?

Solution. It is isomorphic to $\mathbb{Z}^3$. Each component contributes one independent zero-dimensional class.

- (b) **Exercise 2.** What is $H_1(S^1)$?

Solution. It is $\mathbb{Z}$. One generator is the loop going once around the circle; going around twice represents twice that generator.

- (c) **Exercise 3.** Why is a boundary always a cycle?

Solution. Because $\partial^2 = 0$. If $b = \partial c$, then $\partial b = \partial(\partial c) = 0$.

- (d) **Exercise 4.** What does torsion $\mathbb{Z}_2$ in homology mean geometrically?

Solution. It means a nonzero class becomes zero after being added to itself twice. The projective plane has an essential loop with exactly this behavior.

- (e) **Exercise 5.** Why can homology fail to distinguish two spaces?

Solution. Homology records cycles and boundaries but forgets some information about how loops interact. Spaces can share all homology groups while having different fundamental groups or geometric shapes.

Chapter 38

Homotopy theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. When should two maps or spaces be considered the same if one can be continuously deformed into the other?

Formal

Homotopy theory studies continuous deformation. It replaces exact equality by a controlled notion of sameness and then builds algebraic invariants, higher-dimensional operations, and abstract models of spaces.

2. History

Historical development

(a) **The central idea.**

Two continuous maps $f, g : X \rightarrow Y$ are homotopic if there is a continuous family $H : X \times [0, 1] \rightarrow Y$ with $H(x, 0) = f(x)$ and $H(x, 1) = g(x)$. A rubber band on a tabletop can move

continuously without cutting; homotopy regards the starting and ending placements as equivalent. A circle cannot be continuously shrunk to a point while remaining in the punctured plane, because the missing point creates an obstruction [1].

Homotopy theory began in algebraic topology but is now an independent subject. It studies spaces, maps, homotopies between maps, and homotopies between those homotopies. The emphasis is not on coordinates but on what survives deformation.

3. Theory

Core theory

128. Spaces, maps, and fundamental groups.

A path is a map from an interval. A loop starts and ends at the same point. Homotopy classes of loops based at a point form the fundamental group $\pi_1(X)$. Multiplication follows one loop after another; the inverse runs a loop backward. The fundamental group of a circle is $\mathbb{Z}$, while the sphere has trivial fundamental group.

Higher homotopy groups use maps from spheres: $\pi_n(X)$ records maps $S^n \rightarrow X$ up to homotopy. Unlike the fundamental group, higher groups are abelian for $n \geq 2$. They detect higher-dimensional twisting, but are usually much harder to compute.

129. Worked example: fundamental groups of S^1 and T^2 .

The circle S^1 . Consider the universal covering map $\mathbb{R} \rightarrow S^1$ given by $t \mapsto e^{2\pi it}$. A loop in S^1 based at 1 lifts to a path in $\mathbb{R}$ starting at 0 and ending at some integer $n \in \mathbb{Z}$. Two loops are homotopic if and only if they lift to paths ending at the same integer, so $\pi_1(S^1) \cong \mathbb{Z}$, with the integer recording winding number.

The torus $T^2 = S^1 \times S^1$. A loop in the product decomposes as a pair of loops, one in each factor. Hence

$$\pi_1(T^2) \cong \pi_1(S^1) \times \pi_1(S^1) \cong \mathbb{Z} \times \mathbb{Z}.$$

Geometrically, a loop that goes once around the meridian represents $(1, 0)$ and a loop going once around the longitude represents $(0, 1)$. Every homotopy class is an integer combination of these two

generators. In contrast, the sphere S^2 has $\pi_1(S^2) = 0$ because every loop on a sphere can be shrunk to a point—there are no “holes” to wind around.

130. Homotopy equivalence and examples.

Spaces X and Y are homotopy equivalent if maps exist in both directions whose composites are homotopic to the identity. A disk is homotopy equivalent to a point; a cylinder is homotopy equivalent to a circle; a torus is not equivalent to a sphere because their loops and homology differ.

Weak homotopy equivalence requires isomorphisms on all homotopy groups and components. Under suitable hypotheses, such as CW complexes, weak equivalence implies homotopy equivalence. This distinction prevents pathological spaces from misleading the theory.

131. Loops, suspensions, and adjunction.

The loop space ΩX consists of based loops in X , with multiplication by concatenation. The suspension ΣX joins two cones over X . Looping and suspending are related by

$$[\Sigma X, Y] \cong [X, \Omega Y],$$

where brackets denote homotopy classes of maps. Milnor’s theorem says that if X has the homotopy type of a CW complex, so does ΩX [2].

The suspension operation creates stable phenomena. Stable homotopy theory studies what becomes constant after repeated suspension. Spectra package sequences of spaces and their structure maps, and generalized cohomology theories are represented by spectra.

132. Bundles and classifying spaces.

For a topological group G , a principal G -bundle over X is classified by a map to a classifying space BG . Homotopy classes of maps satisfy

$$[X, BG] \cong \{\text{principal } G\text{-bundles over } X\}/\text{isomorphism}.$$

The universal bundle over BG pulls back along a map $X \rightarrow BG$ to produce every principal bundle. Brown’s representability theorem explains why many cohomology theories can be represented by spaces.

Eilenberg–Mac Lane spaces satisfy $[X, K(A, n)] = H^n(X; A)$. Thus ordinary cohomology itself can be expressed as a homotopy classification problem [3].

133. Model categories and simplicial sets.

Model category theory provides three classes of maps: weak equivalences, cofibrations, and fibrations. It allows constructions to be performed up to homotopy while keeping enough algebraic control. Topological spaces and nonnegative chain complexes are model categories.

A simplicial set is a sequence of sets of abstract simplices with face and degeneracy maps. It generalizes a simplicial complex and can serve as a combinatorial model of a space. The singular simplicial set of X has as its n -simplices all maps from the standard n -simplex to X ; its associated chain complex computes singular homology. Geometric realization turns a simplicial set into a CW complex.

134. Other mathematical settings.

Algebraic geometry has $\mathbb{A}^1$ -homotopy theory, where the affine line plays the role of an interval. Category theory uses higher categories and infinity-categories to record objects, maps, homotopies, and higher homotopies. Noncommutative geometry uses KK-theory and noncommutative topology to extend homotopy ideas beyond ordinary spaces.

135. What the theory depends on and where it is useful.

Homotopy theory depends on topology, algebraic topology, category theory, algebraic structures, and often homology and cohomology. It helps classify fiber bundles, organize generalized cohomology, compare algebraic varieties, and express higher categorical structure.

The theory has a cost: exact homotopy groups can be difficult or impossible to calculate directly, and a homotopy invariant deliberately forgets metric information. It is suited to questions of continuous deformation, not to measuring lengths or angles.

4. Important theorems and results

- (a) **Whitehead theorem.** A weak homotopy equivalence between CW complexes is a homotopy equivalence.
- (b) **Seifert–van Kampen theorem.** Under suitable conditions, the fundamental group of a union is obtained from the groups of its pieces and intersection.
- (c) **Hurewicz theorem.** Under connectivity hypotheses, the first nonzero homotopy group maps isomorphically to the first nonzero homology group.
- (d) **Brown representability theorem.** Suitable cohomology theories are represented by spaces.
- (e) **Freudenthal suspension theorem.** In a stable range, suspension gives isomorphisms between successive homotopy groups [4].

136. Applications.

- (a) **Robotics and configuration spaces.** The configuration space of a rigid robot arm with multiple revolute joints is a product of circles, and the homotopy type of this space determines which motions are continuously deformable into one another. When obstacles are present, the configuration space becomes a manifold with boundary, and its fundamental group π_1 classifies the distinct ways the arm can circumnavigate obstacles without collision. Two joint trajectories are homotopic precisely when one can be continuously deformed into the other through collision-free motions. This classification is used in motion planning algorithms: by computing generators of π_1 for the obstacle-free configuration space, planners identify qualitatively different route classes and select the shortest representative in each class. For multi-robot systems, the joint configuration space is a product of many circle factors, and its higher homotopy groups detect topological obstructions to coordinating three or more robots simultaneously around shared obstacles [1, 3].
- (b) **Sensor networks and coverage.** In a network of mobile sensors, the sensing region swept out over time forms a topological space whose homotopy groups characterize coverage

redundancy. A loop of sensors that cannot be contracted without uncovering a region signals a coverage gap, detected as a nontrivial element of π_1 . Higher homotopy groups detect volumetric voids in three-dimensional sensor deployments. When sensors move along planned trajectories, the homotopy class of each trajectory relative to obstacles determines whether the sensor can be rerouted without leaving its assigned coverage area. This framework extends persistence-based methods: while persistent homology records the birth and death of topological features across scales, homotopy-theoretic invariants classify the qualitative ways in which trajectories, not just static coverage, can be deformed. Researchers have applied these ideas to underwater sensor networks for tsunami monitoring, where the ocean floor creates obstacles that force sensors into nontrivial homotopy classes, and to drone swarms for agricultural surveying, where the homotopy type of the free space determines the minimum number of distinct flight patterns needed to cover a field [2, 3].

6. Connections

Using existing theories

- (a) Topology supplies continuous maps and deformation, while algebraic topology supplies fundamental groups, homology, and homotopy groups.
- (b) Category theory and higher algebra organize suspension, loop spaces, spectra, and representability.

Helping other theories

- (a) Homotopy theory helps classify spaces up to flexible equivalence and provides the language of stable phenomena in algebraic topology.
- (b) It also supports homological algebra, derived geometry, mathematical physics, and the study of higher categories.
- (c) **Robotics and configuration spaces.** The space of configurations of a rigid robot arm is a configuration space whose

topology is governed by homotopy groups. If n points move in the plane without collision, the configuration space has nontrivial fundamental group—the pure braid group—and homotopy theory determines which motions of the arm are continuously deformable into others. This is essential for motion planning: a path in configuration space that cannot be contracted to a point corresponds to a movement that cannot be simplified, which directly affects algorithmic efficiency.

- (d) **Sensor network coverage.** A network of sensors in a region covers the area if every point is within range of at least one sensor. The nerve of the covering—a simplicial complex recording which sensor ranges overlap—has the same homotopy type as the covered region under suitable assumptions. Homotopy-theoretic invariants of the nerve detect holes in coverage: a nontrivial fundamental group or higher homotopy group signals an uncovered region that must be addressed.

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1.** Why is a disk homotopy equivalent to a point?
Solution. Collapse every point of the disk along a straight line to its center. The collapse varies continuously and gives a deformation retraction.
- (b) **Exercise 2.** What is $\pi_1(S^1)$?
Solution. It is $\mathbb{Z}$. A loop is classified by its integer winding number, positive or negative according to direction.
- (c) **Exercise 3.** Why is the punctured plane not simply connected?
Solution. A loop winding once around the missing point cannot be continuously contracted without crossing that point. Its winding number is a nonzero obstruction.
- (d) **Exercise 4.** What does a classifying space classify?

Solution. Homotopy classes of maps into BG correspond to isomorphism classes of principal G -bundles over the source space.

- (e) **Exercise 5.** Why use simplicial sets?

Solution. They encode spaces by combinatorial data while retaining face and degeneracy operations. This makes homotopy constructions accessible to algebra and computation.

Chapter 39

Ideal theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How can arithmetic facts about divisibility be generalized from integers to complicated rings?

Formal

An ideal is a subset of a ring closed under addition and subtraction and absorbing multiplication by any ring element. Ideals make quotient rings possible and allow prime factorization to be studied when elements themselves do not factor uniquely.

2. History

Historical development

(a) **Richard Dedekind.**

Dedekind introduced ideals to restore unique factorization at the level of ideal products in algebraic number rings, even when elements themselves factor ambiguously.

(b) **Emmy Noether and David Hilbert.**

Noether developed structural methods for ideals and ascending chain conditions. Hilbert's basis theorem proved finite generation of ideals in polynomial rings, making ideal theory central to commutative algebra and algebraic geometry [1].

3. Theory

Core theory

137. The problem and the definition.

In the integers, the multiples of 6 form a set closed under addition and multiplication by any integer. The multiples of 6 are written (6) . More generally, an ideal I of a ring R is an additive subgroup such that $rx \in I$ whenever $r \in R$ and $x \in I$. In a noncommutative ring one distinguishes left, right, and two-sided ideals; in a commutative ring they coincide [1].

The zero ideal contains only 0, and the unit ideal is the whole ring. An ideal generated by one element is principal. The ideal generated by a set consists of all finite ring combinations of those generators. In $\mathbb{Z}$, every ideal is (n) for a unique nonnegative integer n , but this simple behavior fails in many rings.

138. Quotient rings.

An ideal is exactly the kind of subset that permits a quotient ring R/I . Two elements are considered equal in the quotient when their difference lies in I . For example,

$$\mathbb{Z}/(n)$$

is arithmetic modulo n . The quotient $\mathbb{Z}/(6)$ identifies numbers with the same remainder after division by 6.

The analogy with group theory is important: normal subgroups produce quotient groups, while two-sided ideals produce quotient rings. The first isomorphism theorem says that the quotient by the kernel of a ring homomorphism is isomorphic to its image.

139. Prime and maximal ideals.

In a commutative ring, a proper ideal $\mathfrak{p}$ is prime if $ab \in \mathfrak{p}$ implies $a \in \mathfrak{p}$ or $b \in \mathfrak{p}$. Equivalently, $R/\mathfrak{p}$ is an integral domain. A proper ideal $\mathfrak{m}$ is maximal if no proper ideal lies strictly between it and R . Equivalently, $R/\mathfrak{m}$ is a field. Every maximal ideal is prime.

In $\mathbb{Z}$, (p) is prime exactly when p is a prime number. In the polynomial ring $k[x, y]$, the ideal (x) is prime because the quotient is $k[y]$, while (x, y) is maximal because the quotient is k . The prime ideals of a polynomial ring can be viewed as algebraic geometric locations.

140. Ideal operations and localization.

For ideals I and J , the sum $I + J$ contains all $a + b$ with $a \in I$ and $b \in J$. The product IJ consists of finite sums of products ab with $a \in I$, $b \in J$. The intersection $I \cap J$ contains elements common to both.

Localization makes selected elements invertible. Localizing a ring at the complement of a prime ideal focuses attention near one algebraic point. A local ring has one maximal ideal and is the algebraic analogue of looking through a microscope at a single location. Primary decomposition expresses an ideal as an intersection of primary ideals, revealing the prime components and multiplicities [2].

141. Factorization and arithmetic.

Unique factorization can fail in the ring of algebraic integers of a number field. Ideals repair this failure: every nonzero ideal in the ring of integers of a number field factors uniquely into prime ideals. The ideal class group measures which ideals are principal. Its finiteness is a central theorem of algebraic number theory.

Fractional ideals are finitely generated modules inside the quotient field, after allowing denominators. A fractional ideal is invertible when another fractional ideal multiplies with it to give the whole ring. In Dedekind domains every nonzero fractional ideal is invertible, which makes ideal arithmetic especially well behaved.

142. Geometry of ideals.

An ideal $I \subseteq k[x_1, \dots, x_n]$ defines its zero set

$$V(I) = \{a : f(a) = 0 \text{ for every } f \in I\}.$$

Thus an ideal is a collection of equations and $V(I)$ is their common solution set. Conversely, polynomials vanishing on a set form an ideal. Hilbert's Nullstellensatz links these operations: over an algebraically closed field, radical ideals correspond to algebraic sets. The ideal $(x^2 + y^2 - 1)$ describes a circle over the real numbers. The ideal (x, y) describes the origin. Prime ideals correspond to irreducible algebraic pieces, maximal ideals to points in affine algebraic geometry. Gröbner bases give an algorithm for membership, elimination, intersection, and solving polynomial systems [3].

143. Modules and noncommutative variants.

An ideal is an R -module contained in R . Module language makes ideal operations systematic and permits generalizations to submodules, annihilators, and Fitting ideals. In noncommutative rings, left and right ideals may differ, and a two-sided ideal is needed for an ordinary quotient ring. One-sided ideals are important in representation theory and operator algebras.

144. What the theory depends on and where it is useful.

Ideal theory depends on ring theory, modules, divisibility, and polynomial algebra. It helps dimension theory by organizing prime chains, algebraic geometry by encoding varieties, number theory by restoring unique factorization for ideals, and elimination theory by representing polynomial constraints.

The word "ideal" is unrelated to an ideal in order theory, though both use closure ideas. Ideal arithmetic may be more abstract than element arithmetic, but that abstraction is precisely what preserves factorization and geometry.

4. Important theorems and results

- (a) **Correspondence theorem.** Ideals of R/I correspond to ideals of R containing I .
- (b) **Chinese remainder theorem.** If I and J are comaximal, then $R/(I \cap J) \cong R/I \times R/J$.
- (c) **Hilbert basis theorem.** If R is Noetherian, then $R[x]$ is Noetherian; in particular every ideal in a polynomial ring over a field is finitely generated.

- (d) **Nullstellensatz.** Radical ideals over an algebraically closed field correspond to algebraic sets.
- (e) **Unique ideal factorization.** Every nonzero ideal in a Dedekind domain factors uniquely into prime ideals [4].

These theorems explain why ideals replace elements when unique factorization of elements fails. The correspondence theorem transfers quotient questions between R and R/I ; the Chinese remainder theorem separates independent congruence conditions; Noetherianity guarantees finite descriptions; and the Nullstellensatz connects radical ideals with geometric solution sets. Unique ideal factorization restores a controlled form of prime decomposition in Dedekind domains.

5. Applications

Ideals encode divisibility and polynomial constraints, and quotient and localization operations turn those constraints into arithmetic and geometric information.

- (a) Ring theory
- (b) algebraic geometry
- (c) algebraic number theory
- (d) commutative algebra
- (e) and polynomial equations.

6. Connections

Using existing theories

- (a) Ring theory supplies ideals, quotient rings, and homomorphisms; commutative algebra supplies prime and maximal ideals; and algebraic geometry interprets ideals as polynomial conditions.
- (b) Number theory adds ideal factorization in rings of integers.

Helping other theories

- (a) Ideal theory helps solve polynomial equations, construct quotient structures, and measure factorization when elements do not factor uniquely.
- (b) It is also the algebraic foundation for schemes, algebraic number theory, and many computational methods.

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1.** Why do the multiples of 6 form an ideal of $\mathbb{Z}$?
Solution. The sum or difference of two multiples of 6 is a multiple of 6, and multiplying a multiple of 6 by any integer remains a multiple of 6.
- (b) **Exercise 2.** Is (5) a maximal ideal of $\mathbb{Z}$?
Solution. Yes. The quotient $\mathbb{Z}/(5)$ is the field with five elements, so (5) is maximal and therefore prime.
- (c) **Exercise 3.** What geometric set is defined by (x, y) in $k[x, y]$?
Solution. It is the single point $(0, 0)$, because both x and y must vanish there.
- (d) **Exercise 4.** Why are prime ideals useful for factorization?
Solution. The quotient by a prime ideal is a domain, so multiplication has no zero divisors there. Prime ideals also serve as the basic factors in ideal factorizations.
- (e) **Exercise 5.** What problem does localization solve?
Solution. It allows selected nonzero elements to become invertible, so one can study algebraic behavior near a chosen prime ideal without carrying unrelated global information.

Chapter 40

Index theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How can the difference between solutions and obstructions of a differential equation be computed from topology?

Formal

The index of a Fredholm operator is the dimension of its kernel minus the dimension of its cokernel. The Atiyah–Singer theorem identifies this analytic integer with a topological expression.

2. History

Historical development

(a) The problem and history.

An equation $Du = f$ may have solutions, many solutions, or no solution for some right-hand sides. The kernel contains solutions of $Du = 0$. The cokernel records the independent

compatibility conditions that f must satisfy. For a Fredholm operator, both spaces are finite-dimensional and

$$\operatorname{ind}(D) = \dim \ker D - \dim \operatorname{coker} D.$$

Israel Gel'fand asked whether this integer could be expressed using topological data. Michael Atiyah and Isadore Singer answered yes in the 1960s [1, 2].

3. Theory

Core theory

145. Why the difference is stable.

The dimensions of the kernel and cokernel can jump when an operator is perturbed. Their difference often does not. On a circle, the operator $D = d/dx - \lambda$ on periodic functions has a nonzero kernel only for special values of λ , but its index remains zero because the adjoint has a matching kernel.

Elliptic operators on compact manifolds are Fredholm. Ellipticity means that the highest-order part of the operator has no hidden direction in which information can propagate without control. Compactness prevents infinitely many independent low-energy solutions.

146. Symbols and the Atiyah–Singer formula.

The leading derivative part of an elliptic operator is its symbol. The symbol is a bundle map on the cotangent bundle and is invertible away from the zero covector. Its homotopy class defines a K-theory element. The analytic index depends only on this topological symbol class.

The Atiyah–Singer index theorem states

$$\operatorname{ind}_{\text{an}}(D) = \operatorname{ind}_{\text{top}}(D).$$

The topological side is built from characteristic classes of the manifold and bundles. One can therefore count analytic zero modes without solving the differential equation explicitly.

147. Major special cases.

The Riemann–Roch theorem computes the dimension difference between holomorphic sections and obstructions. The Hirzebruch–Riemann–Roch theorem extends it to complex manifolds. The signature theorem expresses the signature of the intersection form using the L -class. The Chern–Gauss–Bonnet theorem computes the Euler characteristic from curvature. The Dirac operator yields the $\hat{A}$ -genus and spin-geometric results [3].

148. **Proof viewpoints and applications.**

Atiyah and Singer first used K -theory and a push-forward construction, reducing the problem to spheres. Cobordism gives another reduction to simple generators. A heat-equation proof writes the index as a difference of traces of heat operators; the small-time asymptotic expansion reveals the characteristic classes. Supersymmetry explains cancellations in the heat expansion.

Index theory counts zero modes in gauge theory, instantons, and quantum field theory. It gives dimensions of moduli spaces, integrality constraints such as Rokhlin-type results, and topological information from elliptic boundary problems. The Atiyah–Patodi–Singer theorem adds boundary correction terms involving eta invariants.

149. **What the theory depends on and where it is useful.**

Index theory depends on functional analysis, elliptic PDE, differential geometry, topology, K -theory, and characteristic classes. It helps Hodge theory identify harmonic forms, geometry compute invariants, and physics count stable states.

The index does not usually give the separate dimensions of the kernel and cokernel. On noncompact spaces or for non-elliptic operators, finite-dimensionality and stability may fail; boundary conditions must then be chosen carefully.

4. Important theorems and results

- (a) **Atiyah–Singer index theorem.** The analytic and topological indices of an elliptic operator on a compact manifold are equal.
- (b) **Riemann–Roch theorem.** A holomorphic dimension difference is computed by degree and genus.

- (c) **Chern–Gauss–Bonnet theorem.** The Euler characteristic is the integral of a curvature characteristic form.
- (d) **Hirzebruch signature theorem.** The signature of a compact oriented manifold is an integral of its L -class.
- (e) **Atiyah–Patodi–Singer theorem.** Elliptic index formulas on manifolds with boundary include a boundary spectral correction [4].

The index is an integer that measures an analytic imbalance, such as the difference between the dimensions of a kernel and a cokernel. Atiyah–Singer says that this analytic count equals a topological expression, so it can be computed without solving the differential equation directly. Riemann–Roch, Gauss–Bonnet, and the signature theorem are important special cases; Atiyah–Patodi–Singer shows what changes when a boundary contributes spectral information.

5. Applications

The Fredholm index turns an analytic kernel-minus-cokernel difference into a stable topological quantity under perturbation.

- (a) Elliptic partial differential equations
- (b) geometry
- (c) topology
- (d) heat flow
- (e) quantum physics
- (f) and moduli spaces.

6. Connections

Using existing theories

- (a) Functional analysis supplies operators and spectra, differential geometry supplies elliptic differential operators, and topology supplies characteristic classes and K-theory.

- (b) Measure and integration theory provide the analytic index, while homological algebra organizes the associated complexes.

Helping other theories

- (a) Index theory helps compute analytic quantities from topological data in geometry and mathematical physics.
- (b) It explains why a problem involving infinitely many analytic modes can have a finite, stable integer answer.

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1.** What does the index measure?

Solution. It is the number of independent homogeneous solutions minus the number of independent compatibility conditions for the inhomogeneous equation.

- (b) **Exercise 2.** Why is the index often more stable than kernel dimension?

Solution. Kernel and cokernel dimensions can change together under a perturbation, so their difference can remain constant even when each dimension jumps.

- (c) **Exercise 3.** Why is ellipticity important?

Solution. It supplies analytic control of high-frequency behavior and, on a compact manifold, makes the operator Fredholm with finite-dimensional kernel and cokernel.

- (d) **Exercise 4.** What does the symbol remember?

Solution. It remembers the leading derivative behavior of the operator. Its topological class determines the index even when lower-order terms change.

- (e) **Exercise 5.** Why is the theorem useful if solving the PDE is hard?

Solution. The index can be computed from topology and characteristic classes, giving the difference of solution and obstruction dimensions without finding every solution.

Chapter 41

Information theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How can uncertainty, storage, and communication be measured, and how can messages survive compression and noise?

Formal

Information theory treats information as the resolution of uncertainty. It gives limits for representing data, sending it through a noisy channel, and recovering it reliably.

2. History

Historical development

(a) **History and the communication problem.**

Claude Shannon formalized information theory in 1948 at Bell Labs. Harry Nyquist had related transmission speed to the number of signal levels, and Ralph Hartley had measured the number of distinguishable symbol sequences. Shannon's

Figure 41.1: Information and coding theory follow a message through encoding, noise, and decoding.

problem was simple to state: reproduce at one place a message selected at another, even when the channel adds noise [1].

The theory separates three jobs. Source coding removes predictable repetition so a message takes fewer symbols. Channel coding adds carefully designed redundancy so the receiver can correct errors. Cryptographic coding hides information from an unwanted receiver. The mathematics is based on probability, statistics, and logarithms.

3. Theory

Core theory

150. Information and entropy.

If an event has probability p , its self-information is

$$I(p) = -\log_2 p.$$

A rare event tells us more when it occurs. For a random variable X with probabilities p_i , Shannon entropy is

$$H(X) = -\sum_i p_i \log_2 p_i.$$

It measures average uncertainty before the outcome is known. A fair coin has entropy 1 bit; a coin that always lands heads has entropy 0. The binary entropy function

$$H_b(p) = -p \log_2 p - (1 - p) \log_2 (1 - p)$$

is largest at $p = 1/2$.

The logarithm base determines units: bits or shannons for base two, nats for the natural logarithm, and hartleys for base ten. Entropy is

largest when all possible symbols are equally likely. For independent variables, joint entropy adds; for dependent variables, knowing one reduces uncertainty about the other.

151. Conditional and mutual information.

Conditional entropy $H(X | Y)$ measures uncertainty about X after Y is known. Mutual information is

$$I(X; Y) = H(X) - H(X | Y).$$

It measures how much observing Y teaches us about X . If two variables are independent, mutual information is zero. In a medical test, X may be whether a disease is present and Y a test result; mutual information measures the average reduction in diagnostic uncertainty.

The Kullback–Leibler divergence compares a proposed distribution with the true distribution:

$$D(P\|Q) = \sum_x P(x) \log \frac{P(x)}{Q(x)}.$$

It is nonnegative but not symmetric, so it is a divergence rather than an ordinary distance. Directed information measures information flowing from a past sequence to a future sequence and is useful for channels with memory.

152. Source coding and compression.

The source coding theorem says that a long sequence from a stationary source can be compressed to approximately its entropy rate bits per symbol, but not reliably below that rate. Huffman and arithmetic coding approach this limit for practical sources. ZIP files exploit repeated patterns; images, sound, and video use models of visual or auditory redundancy.

If a source has n equally likely symbols, its entropy is $\log_2 n$. If symbols are correlated, a compressor predicts the next symbol from the previous ones and stores only the surprise. Lossless compression reconstructs the exact data. Lossy compression permits a controlled distortion to achieve a much smaller representation.

153. Noisy channels and capacity.

A channel maps an input symbol to a random output. Its capacity is the greatest rate at which information can be transmitted with arbitrarily small error probability using long codes. Shannon's noisy-channel coding theorem says that rates below capacity are achievable, while rates above capacity are not [2].

For a binary symmetric channel that flips a bit with probability p , the capacity is $1 - H_b(p)$ bits per use. For a band-limited Gaussian channel with bandwidth B , signal power S , and noise power N , the Shannon–Hartley law gives

$$C = B \log_2(1 + S/N).$$

Capacity is a limit, not a promise that every short practical code reaches it.

154. Codes, redundancy, and cryptography.

Error-correcting codes deliberately add redundancy. A repetition code sends 0 as 000 and 1 as 111; a majority vote corrects one error but uses bandwidth inefficiently. Hamming, Reed–Solomon, convolutional, turbo, and low-density parity-check codes approach capacity much more effectively. They made compact discs, mobile phones, DSL, satellite communication, and Voyager data possible [3].

Cryptography uses codes and ciphers to control who can recover a message. Information-theoretic secrecy asks for security even against unlimited computation; the one-time pad achieves it when used correctly. Computational cryptography instead relies on hard problems such as discrete logarithms. Information theory also studies cryptanalysis, secrecy capacity, and leakage from side channels.

155. Applications across science.

In statistics, entropy and divergence measure model fit and guide inference. In machine learning, cross-entropy trains probabilistic predictors, while mutual information measures feature relevance. In neuroscience, information measures how a neural response reveals a stimulus. In bioinformatics it studies molecular codes and sequence evolution. In physics, thermodynamic entropy, black-hole entropy, Landauer's principle, and quantum information connect information to energy and matter.

Other applications include seismic exploration, signal processing, pattern recognition, anomaly detection, music and art analysis, imaging design, information retrieval, plagiarism detection, intelligence gathering, semiotics, and the study of biological and social networks [4].

156. **What the theory depends on and where it is useful.**

Information theory depends on probability, statistics, logarithms, coding, and optimization. It helps coding theory design explicit codes, statistics quantify uncertainty, cryptography analyze secrecy, and machine learning compare distributions. Its model of information is mathematical and probabilistic; it does not by itself measure meaning, truth, or human understanding.

4. Important theorems and results

- (a) **Source coding theorem.** Entropy is the asymptotic lower limit for reliable lossless compression.
- (b) **Noisy-channel coding theorem.** Every rate below channel capacity can be transmitted with error tending to zero using suitable long codes; rates above capacity cannot.
- (c) **Data-processing inequality.** Processing data cannot increase the mutual information it contains about an original variable.
- (d) **Shannon–Hartley law.** Gaussian-channel capacity is $B \log_2(1 + S/N)$.
- (e) **Fano’s inequality.** The probability of decoding error bounds how much uncertainty remains, linking estimation accuracy to information [1].

5. Applications

Entropy, mutual information, and channel capacity quantify uncertainty, compression limits, and the effect of noise.

- (a) Data compression
- (b) error correction

- (c) telecommunication
- (d) statistics
- (e) cryptography
- (f) machine learning
- (g) neuroscience
- (h) and physics.

6. Connections

Using existing theories

- (a) Probability supplies random variables and conditional distributions, while measure theory handles continuous sources.
- (b) Combinatorics and coding theory construct messages, and optimization studies the trade-off between rate, distortion, and reliability.

Helping other theories

- (a) Information theory helps communication, compression, statistics, machine learning, cryptography, and physics quantify uncertainty and dependence.
- (b) Entropy and mutual information are useful only after the source, observation, and noise model have been specified.

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1.** What is the entropy of a fair coin?

Solution. A fair coin has two equally likely outcomes, so its entropy is $H = 1$ bit.

- (b) **Exercise 2.** Why does a certain coin have zero entropy?

Solution. Its outcome is known before the flip. The only probability is 1, and $-\log_2(1) = 0$.

- (c) **Exercise 3.** What does mutual information measure?

Solution. It is the average reduction in uncertainty about one variable after observing another. It is zero when the variables are independent.

- (d) **Exercise 4.** A binary symmetric channel flips bits with probability $p = 0.1$. What is its capacity?

Solution. It is $1 - H_b(0.1)$, approximately $1 - 0.469 = 0.531$ bits per use.

- (e) **Exercise 5.** Why can redundancy improve communication?

Solution. The receiver compares the received word with the structured set of allowed codewords. The pattern of redundant symbols reveals and corrects some errors that an uncoded message could not detect.

Chapter 42

Intersection theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How can the meeting of geometric objects be counted when they touch, overlap, or intersect in high dimensions?

Formal

Intersection theory assigns algebraic multiplicities to intersections and organizes them in rings of cycles. It extends Bezout's counting principle to geometry where ordinary point counting is not enough.

2. History

Historical development

(a) **The problem and its history.**

Two lines in a plane usually meet once. A line and a parabola may meet twice. If the line is tangent, the two meetings merge into one visible point, but the equation still has multiplicity two. Intersection theory preserves this hidden count. Its roots

lie in Bezout's theorem, elimination theory, and the work of Weil and van der Waerden; William Fulton developed a modern framework [1, 2].

For subvarieties A and B of a smooth variety X , a proper intersection has the expected dimension

$$\dim(A \cap B) = \dim A + \dim B - \dim X.$$

The intersection product $A \cdot B$ is a cycle supported on $A \cap B$, with coefficients recording local multiplicity.

3. Theory

Core theory

157. A local example.

The line $y = 0$ and parabola $y = x^2$ meet at the origin. Substituting gives $x^2 = 0$, a double root, so the intersection multiplicity is 2. If the line is moved to $y = \epsilon$, there are two nearby intersection points over the complex numbers, both approaching the origin as ϵ tends to zero. Multiplicity is therefore a continuity-preserving count.

158. Moving cycles and rational equivalence.

Objects in bad position may overlap too much: parallel lines in an affine plane have no meeting, while a plane containing a line has an intersection of unexpectedly high dimension. One moves cycles within a rational-equivalence class until they meet properly. A rational function on a subvariety produces a difference between its zero and pole divisors; such differences are declared equivalent to zero.

The Chow group is the group of cycles modulo rational equivalence. Intersection products make the collection of Chow groups into a Chow ring when the ambient variety is smooth. This ring retains algebraic information that ordinary cohomology may forget.

159. Topological intersection forms.

On an oriented manifold of dimension $2n$, the middle cohomology has a bilinear intersection form

$$\lambda(a, b) = \langle a \smile b, [M] \rangle.$$

It evaluates the cup product on the fundamental class. On a four-manifold this form is especially important: its signature is the number of positive directions minus negative directions. Poincare duality makes the form nondegenerate under suitable hypotheses.

160. Self-intersection and blow-ups.

An object may intersect a moved copy of itself. For a smooth subvariety, the self-intersection is governed by the top Chern class of its normal bundle. A line in the projective plane has self-intersection 1. A ruling line in $\mathbb{P}^1 \times \mathbb{P}^1$ has self-intersection 0 because it can be moved away from itself.

Blowing up a point on a surface replaces the point by an exceptional curve. This curve has genus zero and self-intersection -1 . Castelnuovo's contraction theorem says that a suitable (-1) -curve can be blown down again. These calculations are central in birational classification [3].

161. Modern developments and uses.

Intersection theory counts curves satisfying geometric conditions, such as lines meeting prescribed objects. It underlies enumerative geometry, Chern classes, Riemann–Roch, Gromov–Witten invariants, quantum cohomology, and moduli spaces. Virtual fundamental cycles supply a corrected intersection class when a moduli space is singular or has the wrong dimension. Current developments extend the theory from schemes to stacks and connect it to quantum intersection rings.

162. What the theory depends on and where it is useful.

Intersection theory depends on algebraic geometry, divisors, cycles, commutative algebra, cohomology, and topology. It helps elimination theory count solutions, topology study intersection forms, and physics compute enumerative and quantum invariants.

Nonprojective varieties can lack a well-behaved intersection theory, and singular or nonproper intersections require refined tools such as virtual cycles or derived intersections.

4. Important theorems and results

- (a) **Bezout's theorem.** Plane curves of degrees m and n meet in mn points counted with multiplicity over an algebraically closed field when they have no common component.
- (b) **Moving lemma.** Cycles can often be replaced by rationally equivalent cycles in proper position.
- (c) **Self-intersection formula.** The self-intersection of a smooth subvariety is represented by the top Chern class of its normal bundle.
- (d) **Poincare duality.** The topological intersection pairing on a closed oriented manifold is nondegenerate.
- (e) **Castelnuovo contraction theorem.** A suitable smooth rational curve of self-intersection -1 can be contracted to a smooth point [2].

5. Applications

Cycles, divisors, and refined multiplicities count how geometric objects meet, including intersections invisible in a naive drawing.

- (a) Algebraic geometry
- (b) topology
- (c) enumerative geometry
- (d) moduli spaces
- (e) and mathematical physics.

6. Connections

Using existing theories

- (a) Algebraic geometry supplies varieties, divisors, and local rings; commutative algebra supplies multiplicity; and topology supplies homology and cohomology pairings.
- (b) Chow groups and Chern classes extend the elementary idea of counting intersections.

Helping other theories

- (a) Intersection theory helps algebraic geometry count solutions with multiplicity and helps arithmetic geometry attach numerical invariants to cycles.
- (b) It also connects geometric incidence problems to moduli spaces, enumerative geometry, and characteristic classes.

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1.** Why does $y = x^2$ meet $y = 0$ with multiplicity two at the origin?

Solution. Substitution gives $x^2 = 0$, which has a root of order two. A small parallel displacement produces two nearby complex intersections.

- (b) **Exercise 2.** What is a proper intersection?

Solution. It has the expected dimension: the dimensions add and the ambient dimension is subtracted. No component is unexpectedly large.

- (c) **Exercise 3.** Why move cycles before intersecting?

Solution. A bad position can hide the intended count. Rational equivalence allows a harmless movement to proper position while preserving the intersection class.

- (d) **Exercise 4.** What does self-intersection measure?

Solution. It measures how a subvariety meets a nearby copy of itself and is controlled by the normal bundle describing how it sits in the ambient space.

- (e) **Exercise 5.** Why is a (-1) -curve important?

Solution. It is the exceptional curve created by blowing up a point and can often be contracted, making it a basic step in simplifying a surface.

Chapter 43

Invariant theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. Which quantities remain unchanged when a group transforms the object?

Formal

Invariant theory studies functions that do not change under symmetry. It turns classification up to symmetry into the study of invariant rings, orbit spaces, and geometric quotients.

2. History

Historical development

(a) The question and history.

Suppose a shape is rotated, reflected, or relabeled. Its coordinates change, but some quantities do not. The determinant is unchanged when a matrix is left-multiplied by an element of SL_n , and $x + y$ and xy are unchanged when two variables

are swapped. Invariant theory asks for all such quantities and whether they distinguish different orbits [1].

The subject began with George Boole and Arthur Cayley in the nineteenth century, who studied polynomial forms under linear transformations. It later connected to symmetric functions, representation theory, commutative algebra, moduli spaces, and geometric invariant theory. David Mumford's formulation emphasized constructing quotients of varieties by group actions.

3. Theory

Core theory

163. Group actions and invariant rings.

Let a group G act linearly on a vector space V over a field k . The induced action on polynomial functions $k[V]$ is obtained by transforming the input. The invariant ring is

$$k[V]^G = \{f \in k[V] : f(gv) = f(v) \text{ for every } g \in G, v \in V\}.$$

Each invariant is constant along a group orbit. The orbit is the set of positions reachable from one vector by the symmetry.

For the action of $\mathbb{Z}/2$ sending (x, y) to $(-x, -y)$, the invariant monomials include x^2 , xy , and y^2 . They generate

$$k[x, y]^{\mathbb{Z}/2} \cong k[a, b, c]/(ac - b^2).$$

The relation records that $(x^2)(y^2) = (xy)^2$.

164. Symmetric functions and classical forms.

Swapping variables leaves the elementary symmetric polynomials unchanged. The fundamental theorem of symmetric polynomials says every symmetric polynomial is a polynomial in these elementary ones. For binary quadratic and higher forms, classical invariant theory finds discriminants, determinants, and other polynomial combinations that survive linear changes of variables.

The discriminant of a polynomial is an invariant of its roots: it vanishes exactly when two roots coincide. In geometry, lengths,

angles, areas, and determinants are invariants under different transformation groups. In chemistry, molecular symmetry divides configurations into equivalence classes and predicts allowed transitions.

165. Hilbert's theorems.

For a finite group acting over a field whose characteristic does not divide the group order, averaging over the group gives a Reynolds operator. Hilbert proved finite generation results for invariant rings of important groups. The Hilbert–Nagata theorem says that for a linearly reductive group, the invariant ring of a finitely generated algebra is finitely generated [2].

Finite generation changes an infinite search for invariants into a finite algebraic problem, although finding an explicit generating set may still be difficult. Molien series count invariants by degree for finite groups.

166. Geometric invariant theory.

The orbit space of a group action need not be a nice algebraic variety. Orbits may not be closed, and two different orbits may have closures that meet. Geometric invariant theory keeps the good, closed orbits and identifies points whose closures meet. The invariant ring defines a quotient that captures stable information.

This produces moduli spaces of geometric objects: configurations of points, curves, vector bundles, instantons, and monopoles. Stability conditions exclude degenerate configurations that would make the quotient pathological. Symplectic geometry and equivariant topology developed parallel versions of the same quotient idea [3].

167. What the theory depends on and where it is useful.

Invariant theory depends on group actions, polynomial rings, representation theory, commutative algebra, and algebraic geometry. It helps representation theory decompose spaces, geometry classify shapes, and moduli theory build spaces of objects up to change of coordinates.

Invariants need not separate all orbits. Two genuinely different configurations may share every invariant available in a chosen ring, especially when the group is not reductive or the field has special characteristic. One must therefore state what class of objects the invariants classify.

4. Important theorems and results

- (a) **Fundamental theorem of symmetric polynomials.** Every symmetric polynomial is a polynomial in the elementary symmetric polynomials.
- (b) **Hilbert basis theorem for invariants.** In many reductive settings the invariant ring is finitely generated.
- (c) **Noether bound.** For a finite group in nonmodular characteristic, invariants of bounded degree generate the invariant ring.
- (d) **Hilbert–Mumford criterion.** Stability in geometric invariant theory can be tested using one-parameter subgroups.
- (e) **First fundamental theorem.** For classical groups, specified natural contractions and pairings generate the invariant tensors [4].

5. Applications

Group actions and invariant rings retain polynomial information unchanged by a symmetry and organize quotient or moduli constructions.

- (a) Algebra
- (b) representation theory
- (c) algebraic geometry
- (d) geometry
- (e) robotics
- (f) chemistry
- (g) mechanics
- (h) and moduli spaces.

6. Connections

Using existing theories

- (a) Group actions supply the transformations, ring theory supplies polynomial invariants, and representation theory supplies decompositions into symmetry types.
- (b) Algebraic geometry contributes orbit spaces and geometric invariant theory, while combinatorics provides symmetric functions.

Helping other theories

- (a) Invariant theory helps classify objects up to symmetry, construct coordinates for quotient spaces, and analyze tensors in geometry and physics.
- (b) An invariant can prove that two objects are different, but a complete classification may require several invariants together.

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1.** Why are $x + y$ and xy invariant under swapping x and y ?

Solution. Swapping changes $x + y$ to $y + x$ and xy to yx , which are equal in a commutative polynomial ring.

- (b) **Exercise 2.** What is an orbit?

Solution. It is the set of all points obtainable from one point by applying every element of the acting group.

- (c) **Exercise 3.** Why can the discriminant detect repeated roots?

Solution. It is a symmetric polynomial in the roots that contains a factor $(r_i - r_j)^2$ for every pair. It vanishes exactly when two roots coincide.

- (d) **Exercise 4.** Why is finite generation useful?

Solution. It says all invariant polynomials can be built from finitely many basic ones, so classification can be expressed with a finite coordinate system.

- (e) **Exercise 5.** Why does geometric invariant theory need stability?

Solution. Without stability, different nonclosed orbits can have intersecting closures, so the naive orbit space may fail to be separated or algebraic. Stability selects a well-behaved quotient.

Chapter 44

Iwasawa theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. What happens to arithmetic information when a number field is enlarged through an infinite tower?

Formal

Iwasawa theory studies Galois modules, especially ideal class groups, throughout towers of number fields. A single infinite module records how arithmetic invariants grow at every finite level.

2. History

Historical development

(a) **History and motivation.**

Kenkichi Iwasawa began the theory in 1959 while studying cyclotomic fields. The p -part of an ideal class group measures a failure of unique factorization and was connected by Kummer to the difficulty of Fermat's Last Theorem. Instead of studying

one field at a time, Iwasawa studied an infinite tower and asked for a law governing the class groups at all levels [?, ?].

3. Theory

Core theory

168. The basic tower.

Fix a prime p . A $\mathbb{Z}_p$ -extension of a number field F is an infinite Galois extension F_∞/F whose Galois group is the additive group $\mathbb{Z}_p$. It has finite layers

$$F = F_0 \subset F_1 \subset F_2 \subset \cdots \subset F_\infty$$

with $\text{Gal}(F_n/F) \cong \mathbb{Z}/p^n\mathbb{Z}$. The group $\mathbb{Z}_p$ is the inverse limit of the finite cyclic groups, so the infinite tower is assembled from finite approximations.

169. Concrete illustration: $\mathbb{Z}_p$ -extensions of $\mathbb{Q}$.

The simplest tower to visualize starts with $F = \mathbb{Q}$ and a prime p . The cyclotomic $\mathbb{Z}_p$ -extension is obtained by adjoining all p -power roots of unity: set $K_n = \mathbb{Q}(\zeta_{p^{n+1}})$ and let $K_\infty = \bigcup_n K_n$. The Galois group $\text{Gal}(K_\infty/\mathbb{Q})$ contains a subgroup isomorphic to $\mathbb{Z}_p$, obtained by restricting the cyclotomic character. At level n the relevant subfield F_n satisfies $\text{Gal}(F_n/\mathbb{Q}) \cong \mathbb{Z}/p^n\mathbb{Z}$, so $F_0 = \mathbb{Q}$, F_1 is the unique subfield of $\mathbb{Q}(\zeta_{p^2})$ of degree p over $\mathbb{Q}$, and so on. For $p = 5$: F_1 is the degree-5 subfield of $\mathbb{Q}(\zeta_{25})$, generated by the trace $\alpha = \zeta_{25} + \zeta_{25}^2 + \zeta_{25}^3 + \zeta_{25}^4 + \zeta_{25}^5 + \cdots + \zeta_{25}^{24}$ —wait, more precisely $F_1 = \mathbb{Q}(\eta)$ where $\eta = \sum_{i=1}^4 \zeta_{25}^{5i}$. The class number of $F_0 = \mathbb{Q}$ is 1, so the Iwasawa module I_0 is trivial. As one ascends, the p -parts of the class groups I_n can grow, and the Iwasawa algebra $\Lambda = \mathbb{Z}_p[[\Gamma]]$ (with $\Gamma \cong \mathbb{Z}_p$) acts on the inverse limit. The structure theorem then controls the growth: the formula $v_p(|I_n|) = \mu \cdot 5^n + \lambda n + \nu$ predicts how the class-group size eventually behaves at high levels of the tower.

For a cyclotomic example in the standard setup, begin with $K = \mathbb{Q}(\mu_p)$ and adjoin p^{n+1} st roots of unity. The union K_∞ has Galois group $\mathbb{Z}_p$ over the appropriate base. Let I_n be the p -primary part

of the ideal class group of K_n . Norm maps $I_m \rightarrow I_n$ form an inverse system, and $I = \varprojlim I_n$ becomes a module over the Iwasawa algebra

$$\Lambda = \mathbb{Z}_p[[\Gamma]].$$

170. Why the algebra helps.

If Γ is generated topologically by one element, Λ behaves like a two-dimensional regular local power-series ring. The structure theorem for finitely generated torsion Λ -modules describes I through characteristic factors. The resulting invariants, traditionally called μ , λ , and ν , govern the size of class groups at high levels. In a common form,

$$v_p(|I_n|) = \mu p^n + \lambda n + \nu$$

for all sufficiently large n , with conventions depending on the tower.

This formula does not say the class group itself is simple. It says its p -adic size eventually follows a predictable pattern. The infinite object is useful because its module structure explains all finite stages simultaneously.

171. p -adic analysis and the main conjecture.

Kubota and Leopoldt constructed p -adic L-functions by interpolating special values of Dirichlet L-functions and Bernoulli-number data. Iwasawa's main conjecture says, roughly, that the characteristic power series of an arithmetic Λ -module agrees with the p -adic L-function, up to the natural notion of equivalence.

Mazur and Wiles proved the main conjecture for $\mathbb{Q}$ and totally real fields in the 1980s and 1990. Ribet's converse to Herbrand's theorem and Euler systems supplied influential methods. The conjecture connects algebraic growth of class groups with analytic values of L-functions [?].

172. Generalizations.

The Galois group may be a higher-dimensional p -adic Lie group rather than $\mathbb{Z}_p$. Barry Mazur developed Iwasawa theory for abelian varieties. Ralph Greenberg proposed theories for motives. Elliptic-curve Iwasawa theory studies Selmer groups, ranks, and p -adic L-functions; the main conjecture compares a Selmer module with an analytic function.

173. **What the theory depends on and where it is useful.**

Iwasawa theory depends on algebraic number theory, Galois theory, class field theory, p -adic analysis, modules, and L -functions. It helps the study of Fermat-type questions, elliptic curves, special values, and the arithmetic of infinite extensions.

The statements depend strongly on the chosen prime, tower, and module. A main conjecture may be proved in one family but open in another, and the invariants describe asymptotic growth rather than every small finite layer.

4. Important theorems and results

- (a) **Iwasawa structure theorem.** Finitely generated torsion modules over the one-variable Iwasawa algebra admit a controlled decomposition up to finite modules.
- (b) **Class-number growth formula.** In a $\mathbb{Z}_p$ -tower, p -parts of suitable class groups eventually have valuation $\mu p^n + \lambda n + \nu$.
- (c) **Mazur–Wiles main conjecture.** In major cyclotomic cases, the algebraic characteristic element equals the analytic p -adic L -function.
- (d) **Herbrand–Ribet theorem.** Divisibility of Bernoulli-number data is related to nontrivial components of class groups.
- (e) **Ferrero–Washington theorem.** The μ -invariant vanishes for abelian number fields in the cyclotomic setting [?].

5. Applications

p -adic towers and modules measure how arithmetic invariants grow across infinitely many related number fields.

- (a) Cyclotomic fields
- (b) class groups
- (c) p -adic analysis
- (d) p -adic L -functions
- (e) elliptic curves

- (f) motives
- (g) and modern number theory.

6. Connections

Using existing theories

- (a) Algebraic number theory supplies class groups and units, p-adic analysis supplies local arithmetic, and commutative algebra supplies modules over the Iwasawa algebra.
- (b) Galois theory organizes the infinite towers whose arithmetic is compared.

Helping other theories

- (a) Iwasawa theory helps explain the growth of class groups and Selmer groups in infinite extensions.
- (b) Its main conjectures connect algebraic modules with p-adic L-functions, linking arithmetic calculations to analytic information.

Computational number theory and primality testing.

Iwasawa-theoretic invariants provide practical computational tools. The Fermat quotient $q_p(a) = (a^{p-1} - 1)/p \pmod{p}$, which is a building block of p-adic L-functions, can be computed efficiently and used to detect Wieferich primes, primes p satisfying $2^{p-1} \equiv 1 \pmod{p^2}$, a condition relevant to the first case of Fermat's Last Theorem. The λ -invariant of the cyclotomic $\mathbb{Z}_p$ -extension of $\mathbb{Q}$ is tied to Bernoulli-number divisibility via Herbrand's theorem and the Ferrero–Washington theorem: p divides the numerator of a Bernoulli number B_k if and only if p divides the order of a specific component of the class group of $\mathbb{Q}(\zeta_p)$. Algorithms that compute these class-group components (e.g., via the Sagase or Pari/GP software packages) rely on Iwasawa-theoretic structure to organize computations in towers of number fields, making what would be astronomically large explicit-degree computations feasible by working inside the inverse limit.

7. Sample Questions

Exercise reference: [?]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1.** What is a $\mathbb{Z}_p$ -extension?

Solution. It is an infinite Galois extension whose Galois group is the additive p -adic integers, with finite cyclic layers of order p^n .

- (b) **Exercise 2.** Why use an inverse limit of class groups?

Solution. Norm maps connect the finite layers. The inverse limit stores all compatible information in one module on which the Iwasawa algebra acts.

- (c) **Exercise 3.** What does the growth formula describe?

Solution. It describes the eventual p -adic valuation of the size of the class-group part, not the exact group structure at every level.

- (d) **Exercise 4.** What is the role of a p -adic L-function?

Solution. It is the analytic object that interpolates special arithmetic values and, through the main conjecture, mirrors the algebraic module controlling class-group growth.

- (e) **Exercise 5.** Why is Fermat's Last Theorem historically connected to Iwasawa theory?

Solution. Kummer identified p -torsion in cyclotomic class groups as an obstruction to a direct proof. Iwasawa studied how this obstruction changes in cyclotomic towers.

Chapter 45

K-theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How can vector bundles, projective modules, and large matrices be summarized by algebraic invariants?

Formal

K-theory turns direct-sum objects into groups by formally allowing differences. Its functors assign rings or groups to spaces and schemes, preserving structural information that ordinary homology may miss.

2. History

Historical development

(a) **The problem and history.**

Vector bundles over a space can be added by direct sum, but they cannot usually be subtracted. Grothendieck's idea was to enlarge the collection formally so that a difference $[E] - [F]$ becomes meaningful. The resulting group is K-theory. It

was developed by Grothendieck in algebraic geometry and by Atiyah and Hirzebruch in topology [1, 2].

The word K comes from the German word for a vector bundle. K-theory is a generalized cohomology theory. It is also algebraic: higher K-groups study projective modules, matrices, and algebraic relations in rings.

3. Theory

Core theory

174. Topological K-theory.

For a compact Hausdorff space X , isomorphism classes of finite-dimensional vector bundles form an abelian monoid under direct sum. Its Grothendieck completion is $K^0(X)$. A formal difference $[E] - [F]$ is a virtual vector bundle. Tensor product makes $K^0(X)$ a ring.

The Serre–Swan theorem identifies vector bundles over a compact space with finitely generated projective modules over its ring of continuous functions. Thus a topological question about bundles can become an algebraic question about modules. Reduced K-theory removes the contribution of a base point.

175. Worked example: vector bundles on S^1 and S^2 .

The circle S^1 . A complex line bundle over S^1 is classified by a transition function on the overlap of a covering by two intervals. Because $\pi_0(GL_1(\mathbb{C})) = 0$, every complex line bundle on S^1 is trivial, so $K^0(S^1) \cong \mathbb{Z} \oplus \mathbb{Z}$: the rank and the first Chern class $c_1 \in H^2(S^1; \mathbb{Z}) = 0$ carry no additional information beyond rank.

The sphere S^2 . The situation is richer. The Hopf bundle $E_{\text{Hopf}} \rightarrow S^2$ is a complex line bundle with $c_1(E_{\text{Hopf}}) = 1$, and its class generates $\widetilde{K}^0(S^2) \cong \mathbb{Z}$. Every vector bundle on S^2 is a direct sum of copies of the trivial bundle and the Hopf bundle: $E \cong \mathbb{C}^k \oplus E_{\text{Hopf}}^{\oplus m}$, where k is the rank minus m . The reduced K-group $\widetilde{K}^0(S^2) \cong \mathbb{Z}$ is detected by the first Chern class of the Hopf bundle. This illustrates how K-theory encodes the nontrivial twisting that ordinary dimension-counting misses.

176. Algebraic K-theory.

For a ring or scheme, K_0 is generated by finitely generated projective modules or coherent sheaves, with relations from exact sequences. Higher K-groups $K_1, K_2, \dots$ capture invertible matrices, elementary relations, and deeper algebraic structure. Algebraic K-theory has localization sequences, products, and descent results.

In algebraic geometry, K_0 of a smooth projective curve reflects rank and degree. For singular spaces, coherent sheaves and derived categories describe the corrections caused by singularities. Projective bundles, Artinian algebras, isolated quotient singularities, and virtual tangent bundles provide calculable examples [3].

177. Chern characters and virtual geometry.

The Chern character maps K-theory to rational cohomology:

$$\mathrm{ch} : K^0(X) \longrightarrow H^{\mathrm{even}}(X; \mathbb{Q}).$$

It translates direct sums into addition and tensor products into multiplication. Chern classes recover geometric information from a bundle; the Chern character is often easier to use in index formulas.

Virtual bundles describe formal tangent directions when an intersection or moduli space is singular or has an unexpected dimension. For an intersection $Z = Y_1 \cap Y_2$ in a smooth ambient space X , one writes

$$[T_Z]^{\mathrm{vir}} = [T_{Y_1}]|_Z + [T_{Y_2}]|_Z - [T_X]|_Z.$$

This is a bookkeeping device that makes Riemann–Roch and enumerative geometry work in imperfect situations.

178. Bott periodicity and index theory.

Topological K-theory is periodic: iterating suspension by two dimensions returns the same complex K-groups. Bott periodicity is one of the deepest reasons K-theory is computable. The Atiyah–Singer index theorem expresses the index of an elliptic operator through a K-theory class of its symbol.

Grothendieck–Riemann–Roch compares push-forward in K-theory with push-forward in cohomology after applying the Chern character and Todd class. Adams operations provide additional operations that detect how a bundle behaves under tensor powers.

179. **Equivariant and physical applications.**

Equivariant *K*-theory keeps track of a group action as well as a bundle. It is useful for quotients, orbifolds, representation theory, and fixed-point formulas. In string theory, twisted *K*-theory has been proposed to classify D-brane charges and Ramond–Ramond fields. In condensed-matter physics, *K*-theory classifies topological insulators, superconductors, and stable Fermi surfaces [4].

180. **What the theory depends on and where it is useful.**

K-theory depends on vector bundles, modules, homotopy, cohomology, category theory, and algebraic geometry. It helps index theory convert analytic problems to topology, intersection theory handle virtual dimensions, and operator algebras classify projections.

K-theory is a refined invariant, not a complete description of a space or ring. Different objects can have the same *K*-groups, and torsion or higher operations may be required to distinguish them.

4. Important theorems and results

- (a) **Grothendieck group construction.** Every commutative monoid under direct sum has a universal abelian group of formal differences.
- (b) **Serre–Swan theorem.** Vector bundles over a compact Hausdorff space correspond to finitely generated projective modules over continuous functions.
- (c) **Bott periodicity.** Complex *K*-theory is periodic with period two; real *K*-theory has period eight.
- (d) **Grothendieck–Riemann–Roch theorem.** The Chern character translates *K*-theoretic push-forward into a cohomological formula involving the Todd class.
- (e) **Atiyah–Singer theorem.** The analytic index is the image of a *K*-theory symbol under a topological index map [2].

5. Applications

Vector bundles and projective modules are replaced by stable classes, allowing geometric classification to be expressed through algebraic

groups.

- (a) Topology
- (b) algebraic geometry
- (c) operator algebras
- (d) index theory
- (e) physics
- (f) and the classification of topological materials.

6. Connections

Using existing theories

- (a) Algebra supplies projective modules and exact sequences, topology supplies vector bundles and homotopy, and category theory supplies Grothendieck groups and higher constructions.
- (b) Geometry connects bundles, characteristic classes, and index problems.

Helping other theories

- (a) *K*-theory helps classify vector bundles, formulate index theorems, study algebraic cycles, and organize information about modules.
- (b) It packages many stable equivalence questions into groups and spectra that support calculation.
- (c) **Topological insulators in condensed-matter physics.** Topological insulators are materials that are insulating in their interior but support conducting states on their boundary. The classification of free-fermion topological phases in condensed matter is given by *K*-theory of the Brillouin zone. For systems with time-reversal symmetry (class AII), the ten-fold way periodicity of real *K*-theory (period eight by Bott periodicity) predicts exactly which insulating phases exist in each spatial

dimension. The $\mathbb{Z}_2$ invariant distinguishing a topological insulator from a trivial insulator in two dimensions is a K-theory class.

- (d) **C^* -algebra classification.** In operator algebras, the K-theory groups K_0 and K_1 of a C^* -algebra classify projections and unitaries up to stable equivalence. The bootstrap class in C^* -algebra theory uses K-theoretic data to classify simple nuclear C^* -algebras by their K-groups, trace, and the pairing between them. This KK-theory framework, which combines homotopy and K-theory in the noncommutative setting, provides invariants for spaces that cannot be studied with ordinary commutative methods.

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1.** Why are virtual bundles useful?

Solution. They permit subtraction. A formal difference can represent the normal bundle of an embedding or the tangent directions of a virtual intersection even when no honest bundle has that rank.

- (b) **Exercise 2.** What is $K^0(X)$ built from?

Solution. It is the Grothendieck group of isomorphism classes of finite-dimensional vector bundles over X , with direct sum as addition.

- (c) **Exercise 3.** What does Bott periodicity say in plain language?

Solution. After increasing dimension by two in complex K-theory, the pattern of groups repeats.

- (d) **Exercise 4.** Why does the Chern character help?

Solution. It moves a K-theory problem into rational cohomology, where addition, multiplication, and characteristic-class calculations are often simpler.

- (e) **Exercise 5.** What does equivariant *K*-theory remember that ordinary *K*-theory forgets?

Solution. It remembers how a symmetry group acts on the bundle or module, not merely the underlying object.

Chapter 46

Knot theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. When are two tangled loops really the same knot, and how can the difference be detected without untangling them physically?

Formal

Knot theory studies embeddings of circles in three-dimensional space up to ambient deformation. Diagrams, Reidemeister moves, knot groups, polynomials, and geometric invariants turn visual tangling into calculable mathematics.

2. History

Historical development

(a) **Definition and history.**

A mathematical knot is a copy of a circle embedded in $\mathbb{R}^3$; its ends are joined, unlike a shoelace. Two knots are equivalent when one can be carried to the other by a continuous family of

homeomorphisms of space, with no cutting or passing through itself. The untwisted circle is the unknot; the trefoil is the simplest nontrivial knot [1].

Vandermonde and Gauss studied early topological features, including the linking integral. Lord Kelvin's nineteenth-century idea that atoms might be knotted vortices motivated Peter Tait's knot tables. Dehn, Alexander, Reidemeister, Thurston, Jones, Witten, Kontsevich, and Kauffman later introduced algebraic, geometric, and quantum methods.

3. Theory

Core theory

181. Diagrams and Reidemeister moves.

Figure 46.1: Knot and braid diagrams turn strand motion into a mathematical object.

Project a knot to the plane so that crossings are transverse double points. At each crossing, record which strand passes over the other. Different projections of the same knot look different, so one needs diagram moves that preserve the knot.

Reidemeister's three moves are: create or remove a twist; pull one strand across another; and move a strand across a crossing. Two diagrams represent equivalent knots exactly when a finite sequence of these moves connects them. This gives a finite local language for a global deformation [2].

182. Invariants.

A knot invariant gives the same answer for every diagram of an equivalent knot. The knot group is the fundamental group of the

complement of the knot. The Alexander polynomial comes from the infinite cyclic cover of the complement. The Jones and Kauffman polynomials use skein relations and connect knot theory to quantum groups and statistical mechanics.

For the Alexander–Conway polynomial of an oriented link, the unknot has value 1 and a crossing relation has the form $C(L_+) = C(L_-) + zC(L_0)$. Applying it to the trefoil gives $1 + z^2$, different from the unknot, so the trefoil is knotted. The polynomial does not distinguish the left and right trefoils, but the Jones polynomial can distinguish their chirality.

183. **Hyperbolic geometry and higher dimensions.**

Most knots are hyperbolic: their complements admit a complete finite-volume hyperbolic metric. Volume, cusp shape, and other hyperbolic data become invariants. Thurston’s hyperbolization work connected knot complements to three-dimensional geometry.

A higher-dimensional knot is an n -sphere embedded in $(n + 2)$ -dimensional Euclidean space. Links have several components. Tangles have open ends and model local pieces of knots. Knot multiplication joins two knots; prime knots cannot be decomposed nontrivially, and tables use crossing number to organize examples.

184. **Tabulation and computation.**

The Alexander–Briggs notation records crossing number and index. Dowker–Thistlethwaite codes, Conway notation, and Gauss codes encode diagrams in machine-readable form. More than billions of knots and links have been tabulated. Knot recognition has algorithms, including unknot-recognition algorithms, but their practical complexity remains a major question.

185. **Applications.**

DNA and proteins can become knotted or linked. Tangles model the action of topoisomerase enzymes, and knot invariants can distinguish molecular handedness. Polymer physics studies how knots affect elasticity and entanglement. Jones-polynomial ideas inspired topological quantum computation, where protected information is stored in global braiding patterns [3].

186. **What the theory depends on and where it is useful.**

Knot theory depends on topology, group theory, homology, geometry, and combinatorics. It helps low-dimensional topology through knot complements and three-manifolds, quantum topology through polynomial invariants, and biology through molecular tangles.

No single invariant distinguishes every knot. A successful test may prove two knots different but usually cannot prove they are the same without a complete equivalence algorithm.

4. Important theorems and results

- (a) **Reidemeister theorem.** Equivalent knot diagrams are related by the three Reidemeister moves.
- (b) **Alexander polynomial.** The Alexander invariant of a knot complement produces a computable polynomial invariant.
- (c) **Gordon–Luecke theorem.** A knot in the three-sphere is determined by the homeomorphism type of its complement.
- (d) **Thurston hyperbolization.** Many knot complements carry a finite-volume hyperbolic structure.
- (e) **Jones polynomial.** A quantum invariant obtained from a skein relation and capable of detecting chirality in examples [4].

The theorems answer three different questions. Reidemeister moves identify when two drawings represent the same knot; polynomial invariants provide computable tests that can distinguish drawings; and the complement theorems show that the surrounding three-dimensional space can determine the knot itself. Hyperbolic geometry adds measurable structure, such as volume, to many knot complements. None of these invariants is a universal quick classifier, so several must often be combined.

5. Applications

Isotopy classes, knot complements, and invariants distinguish embeddings of circles in three-dimensional space.

- (a) Topology

- (b) DNA and proteins
- (c) polymers
- (d) quantum topology
- (e) statistical mechanics
- (f) and topological quantum computation.

6. Connections

Using existing theories

- (a) Topology supplies embeddings and ambient isotopy, group theory supplies knot groups, and algebraic topology supplies homology and covering spaces.
- (b) Combinatorics and polynomial algebra turn a knot diagram into invariants that can be computed.

Helping other theories

- (a) Knot theory helps study DNA recombination, polymer entanglement, fluid vortices, and three-dimensional manifolds.
- (b) A knot invariant is useful when it separates examples or predicts a property, but one invariant rarely gives a complete classification.

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1.** Why is the unknot different from a knot tied in a rope?

Solution. A mathematical knot is closed: its two ends are joined. A rope can be untied by sliding an end out, while a closed knot cannot use that escape.

- (b) **Exercise 2.** What do Reidemeister moves preserve?

Solution. They preserve the ambient-isotopy class of the knot, even though they change the planar drawing.

- (c) **Exercise 3.** Why can an invariant fail to distinguish knots?

Solution. An invariant is a summary. Different knots may produce the same summary, so several invariants or a deeper complement analysis may be needed.

- (d) **Exercise 4.** What does the knot group describe?

Solution. It describes how loops in the three-dimensional space outside the knot can be combined and deformed.

- (e) **Exercise 5.** Why are tangles useful for DNA?

Solution. A local DNA operation affects a segment with two ends. Tangle diagrams model that local segment and compare the knot or link before and after the operation.

Chapter 47

L-theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How can quadratic forms and algebraic surgery measure whether a manifold can be modified into a desired shape?

Formal

Algebraic L-theory is a K-theory-like study of quadratic and symmetric forms over rings with involution. Its groups store the obstructions that remain after geometric surgery.

2. History

Historical development

(a) **History and motivation.**

Wall introduced algebraic L-theory, using the letter after K. The central problem in surgery theory is to alter a manifold by cutting out a product of disks and gluing another product in its place. Algebra tells us whether the altered object can

become homotopy equivalent or homeomorphic to a target manifold. The obstruction lies in an *L*-group [1].

3. Theory

Core theory

187. Quadratic forms and Witt groups.

A quadratic form assigns a value such as $x^2 + y^2$ or $x^2 - 3y^2$ to a vector. Over a ring with involution, one studies forms compatible with the involution. A form is nondegenerate when its associated pairing has no hidden null direction. Hyperbolic forms represent completely canceling pairs and are treated as trivial after stabilization.

188. Worked example: a quadratic form on $\mathbb{Z}^2$.

Consider the quadratic form $q: \mathbb{Z}^2 \rightarrow \mathbb{Z}$ defined by $q(m, n) = m^2 + n^2$. Its associated bilinear pairing is $b((m, n), (m', n')) = 2mm' + 2nn'$. This form is nondegenerate: if $b((m, n), -) = 0$ for all inputs, then $(m, n) = (0, 0)$. The signature of this form is 2 (both eigenvalues of the corresponding real matrix are positive), so its class in $L_0(\mathbb{Z}) \cong \mathbb{Z}$ is 2.

Now perform surgery: replace the sub-lattice spanned by $(2, 0)$ and $(0, 1)$ with a new copy glued along its boundary sphere. The surgery changes the form by a hyperbolic summand, which is trivial in the Witt group. After stabilization the signature remains 2, and the surgery obstruction in $L_4(\mathbb{Z}) \cong \mathbb{Z}$ is zero: the target manifold can be reached. If instead the surgery produced a form with signature 1, the obstruction class would be nonzero and no sequence of further surgeries would succeed [1, 2].

For a ring R with involution, even-dimensional quadratic groups $L_{2k}(R)$ are Witt groups of suitable $(-1)^k$ -quadratic forms. Addition is orthogonal direct sum. Symmetric *L*-groups $L^n(R)$ use symmetric forms; a symmetrization map relates the two and is an isomorphism away from relevant 2-torsion.

189. Periodicity and the integer example.

Quadratic and symmetric *L*-groups are four-periodic. For the

integers,

$$\begin{aligned} L_{4k}(\mathbb{Z}) &\cong \mathbb{Z}, & L_{4k+1}(\mathbb{Z}) &= 0, \\ L_{4k+2}(\mathbb{Z}) &\cong \mathbb{Z}/2, & L_{4k+3}(\mathbb{Z}) &= 0. \end{aligned}$$

The integer in dimension $4k$ is related to signature, while the $\mathbb{Z}/2$ class in dimension $4k + 2$ is detected by an Arf invariant. These values are the algebraic shadows of geometric surgery obstructions [2].

190. **Surgery and manifold classification.**

Suppose a manifold is equipped with a degree-one normal map to a target. Surgery removes a sphere times a disk and replaces it by a disk times a sphere. Below the middle dimension, surgery can remove homotopy defects. At the middle dimension, an intersection or quadratic form remains. Its class in $L_n(\mathbb{Z}[\pi_1])$ is the obstruction to completing the surgery.

The fundamental group appears through the group ring $\mathbb{Z}[\pi]$, because loops affect how handles are attached. For finite π , algebraic calculations are available; for infinite groups, controlled topology and geometric methods become important.

191. **Algebraic and symmetric versions.**

The quadratic theory remembers a preferred quadratic refinement, while symmetric theory remembers the bilinear form. In characteristic different from two these are closely related; in the presence of 2-torsion they can differ. Ranicki developed formulations for additive categories equipped with chain duality, allowing chain complexes and derived algebra to replace free modules.

192. **What the theory depends on and where it is useful.**

L-theory depends on ring theory, modules, quadratic forms, *K*-theory, homotopy theory, and high-dimensional manifold topology. It helps surgery theory decide whether a homotopy equivalence can be improved to a homeomorphism or diffeomorphism, and helps classification problems by turning geometry into algebra.

The theory is most effective in high dimensions and under hypotheses on the fundamental group. Low-dimensional topology has additional phenomena that are not captured by ordinary surgery obstructions.

4. Important theorems and results

- (a) **Wall surgery obstruction.** A degree-one normal map has an obstruction in an appropriate *L*-group; vanishing is the algebraic condition for surgery continuation.
- (b) **Four-periodicity.** *L*-groups repeat after four dimensions in standard quadratic and symmetric theories.
- (c) **Symmetrization.** Quadratic and symmetric *L*-groups are related by a map that is an isomorphism modulo 2-torsion.
- (d) **Surgery exact sequence.** Structure sets, normal invariants, and *L*-groups occur in an exact sequence organizing manifold classification.
- (e) **Signature and Arf calculations.** For $\mathbb{Z}$, dimensions divisible by four are measured by signature, while dimensions congruent to two carry an Arf-type $\mathbb{Z}/2$ obstruction [1].

5. Applications

Quadratic forms and surgery obstructions convert high-dimensional manifold classification into algebraic calculations.

- (a) Surgery theory
- (b) manifold classification
- (c) quadratic forms
- (d) topology
- (e) algebraic K-theory
- (f) and controlled topology.

6. Connections

Using existing theories

- (a) Algebra supplies quadratic forms and modules, topology supplies manifolds and surgery, and homotopy theory supplies normal invariants.

- (b) The algebraic L-groups record the obstruction left after geometric changes have been made.

Helping other theories

- (a) L-theory helps classify high-dimensional manifolds and analyze whether a homotopy equivalence can be improved to a homeomorphism or diffeomorphism.
- (b) Its periodicity turns an apparently unbounded classification problem into recurring algebraic cases.
- (c) **Three-manifold recognition.** In dimension three, the surgery exact sequence combined with L-theory over the fundamental group ring $\mathbb{Z}[\pi_1]$ provides algebraic criteria that distinguish homotopy-equivalent but non-homeomorphic 3-manifolds. For example, two closed orientable 3-manifolds with isomorphic fundamental groups can be separated by computing their $L_1(\mathbb{Z}[\pi_1])$ surgery obstructions, which detect differences in how handles are attached.
- (d) **Knot concordance.** The algebraic signature of the Seifert matrix of a knot K gives a class in $L_0(\mathbb{Z}) \cong \mathbb{Z}$. For the trefoil knot this signature is $2 \neq 0$, proving it is not slice (not the boundary of a smoothly embedded disk in the 4-ball). L-theory thus provides a computable concordance invariant that separates knots into distinct concordance classes [1, 2].

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1.** What does an L-group classify?
Solution. It classifies stable equivalence classes of suitable nondegenerate quadratic or symmetric forms, and in topology it records surgery obstructions.
- (b) **Exercise 2.** Why are hyperbolic forms treated as trivial?

Solution. They contain paired directions that cancel algebraically. Stabilizing by adding them should not change the essential obstruction.

- (c) **Exercise 3.** Why does the group ring $\mathbb{Z}[\pi]$ appear?

Solution. The fundamental group π records loops in the manifold, and the group ring lets algebra track how those loops act on chains and handles.

- (d) **Exercise 4.** What is the significance of four-periodicity?

Solution. It means the obstruction groups repeat in dimensions four apart, making high-dimensional calculations patterned rather than unrelated.

- (e) **Exercise 5.** Why can quadratic and symmetric L-theory differ?

Solution. A quadratic refinement contains information not determined by a bilinear pairing, especially when two-torsion is present.

Chapter 48

Lattice theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How can a collection of partially ordered objects support both a best common lower bound and a best common upper bound?

Formal

Lattice theory studies ordered systems in which every pair has a meet and a join. It unifies divisibility, subsets, logic, subspaces, ideals, and data dependencies.

2. History

Historical development

(a) **Richard Dedekind.**

Dedekind recognized that substructures such as ideals can be organized by inclusion, with intersection and generated sum acting as meet and join. This made order a useful algebraic description of divisibility and subobjects.

(b) Garrett Birkhoff and Alfred Tarski.

Birkhoff developed lattice theory as an independent algebraic subject and proved representation results for important classes such as distributive lattices. Tarski's fixed-point work showed how complete lattices support existence and iteration arguments in logic and computer science [1].

3. Theory**Core theory****193. The problem and the definition.**

In a partially ordered set, two objects may be comparable or incomparable. A lattice adds two operations. The meet $a \wedge b$ is the greatest object below both of them; the join $a \vee b$ is the least object above both. For sets, meet is intersection and join is union. For integers ordered by divisibility, meet is greatest common divisor and join is least common multiple [1].

The operations satisfy associativity, commutativity, absorption, and idempotence. A lattice may be described by its order or by these two operations. A bounded lattice has a least element 0 and greatest element 1. A complemented lattice gives each element a partner whose meet is 0 and join is 1.

194. Examples.

The power set of a finite set is a Boolean lattice. The subspaces of a vector space form a lattice: meet is intersection and join is vector-space sum. The ideals of a ring form a lattice under intersection and generated sum. Logical propositions form a lattice in which meet means "and" and join means "or".

The divisors of 60 ordered by divisibility form a finite lattice. The meet of 12 and 18 is 6, while their join is 36. A total order, such as the real numbers, is also a lattice: meet is minimum and join is maximum.

195. Distributive and modular lattices.

A lattice is distributive when $a \wedge (b \vee c) = (a \wedge b) \vee (a \wedge c)$ and the dual identity also holds. Boolean lattices are distributive and

support ordinary logic. The lattice of subspaces is usually not distributive but is modular, a weaker identity reflecting dimension. Finite distributive lattices are controlled by their join-irreducible elements. This gives a bridge between an abstract order and a simpler poset of building blocks. Modular and semimodular lattices appear in geometry, matroid theory, and dimension arguments.

196. Completeness and fixed points.

A complete lattice has a meet and join for every subset, not merely every pair. The power set of any set is complete. Complete lattices are important in semantics and program verification because recursive definitions can be interpreted as fixed points.

The Knaster–Tarski theorem says every monotone self-map of a complete lattice has a least and a greatest fixed point. The least fixed point can describe the smallest set of states reachable by a program; the greatest can describe all states satisfying an invariant [2].

197. Homomorphisms and constructions.

A lattice homomorphism preserves meets and joins: $f(a \wedge b) = f(a) \wedge f(b)$ and $f(a \vee b) = f(a) \vee f(b)$. It is automatically order-preserving. Products, sublattices, quotient lattices, ideals, filters, and congruences are standard constructions. A filter is dual to an ideal: it is upward closed and closed under meet.

198. Applications.

Boolean lattices model digital circuits and logical reasoning. In databases, sets of attributes and functional dependencies form closure systems. In version control, a lattice can represent states that have a common merge or common ancestor. In static program analysis, abstract states are ordered by information and fixed points compute loop invariants.

Lattice methods also organize equivalence relations, partitions, subgroups, ideals, and topology. The lattice of open sets is a frame or locale, a foundation for point-free topology and topos theory. Dilworth’s and Mirsky’s theorems connect chains and antichains, while Zorn’s lemma and maximal principles use order structure [3].

199. What the theory depends on and where it is useful.

Lattice theory depends on partial orders, sets, logic, algebra, and universal algebra. It helps order theory describe closure, ring theory organize ideals, type theory interpret propositions, and computer science compute fixed points.

The word lattice also names a periodic grid in geometry and crystallography; that geometric lattice is a different but related subject. In an order lattice, joins and meets may exist abstractly without having a simple numerical formula.

4. Important theorems and results

- (a) **Birkhoff representation theorem.** Every finite distributive lattice is isomorphic to the lattice of lower sets of the poset of its join-irreducible elements.
- (b) **Knaster–Tarski theorem.** Every monotone map of a complete lattice has a complete lattice of fixed points, including least and greatest fixed points.
- (c) **Dilworth’s theorem.** In a finite poset, the largest antichain size equals the minimum number of chains needed to cover the poset.
- (d) **Boolean representation theorem.** Every Boolean algebra is represented by sets, with operations corresponding to union, intersection, and complement.
- (e) **Jordan–Dedekind property.** In a finite graded lattice, all maximal chains between fixed endpoints have the same length [4].

5. Applications

Meet, join, order, and fixed-point operations describe how partial information can be combined or completed.

- (a) Order theory
- (b) algebra
- (c) logic

- (d) computer science
- (e) optimization
- (f) formal verification
- (g) and universal algebra.

6. Connections

Using existing theories

- (a) Order theory supplies partial orders, joins, meets, and duality; set theory supplies concrete lattices of subsets; and algebra supplies ideals, subspaces, and congruences as examples.
- (b) Combinatorics studies chains and antichains.

Helping other theories

- (a) Lattice theory helps logic, computer science, scheduling, data-flow analysis, and the study of subobjects in algebra.
- (b) The order structure records which information refines which, so fixed-point and representation theorems can guide computation.

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1.** In the divisor lattice of 60, find the meet and join of 12 and 18.

Solution. The meet is $\gcd(12, 18) = 6$ and the join is $\text{lcm}(12, 18) = 36$.

- (b) **Exercise 2.** What are meet and join for subsets?

Solution. The meet is intersection, because it is the largest set contained in both. The join is union, because it is the smallest set containing both.

- (c) **Exercise 3.** Why is a total order a lattice?

Solution. Any two elements are comparable. The smaller is their meet and the larger is their join.

- (d) **Exercise 4.** What does the Knaster–Tarski theorem provide in program verification?

Solution. A monotone program transformer has a least fixed point representing the smallest solution of recursive reachability equations and a greatest fixed point representing the largest invariant solution.

- (e) **Exercise 5.** What makes a lattice Boolean?

Solution. It is bounded, distributive, and every element has a complement. The power set of a set is the standard model.

Chapter 49

Lie theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How can continuous symmetries be studied with the same clarity that groups give to discrete symmetries?

Formal

Lie theory studies Lie groups, their infinitesimal Lie algebras, and the actions they generate. The exponential map turns small motions into finite transformations and makes differential equations, geometry, and physics share one language.

2. History

Historical development

(a) History and motivation.

Sophus Lie wanted a theory of continuous transformation groups that would organize differential equations, just as Galois theory organizes polynomial equations. Wilhelm Killing and

Élie Cartan developed the structure and representation theory of semisimple Lie algebras. Lie's work also led to contact geometry, Lie sphere geometry, moving frames, and symmetric spaces [1].

3. Theory

Core theory

200. Groups of continuous motion.

A Lie group is both a group and a smooth manifold, with smooth multiplication and inversion. Rotations of the plane form the circle group. Rotations of three-dimensional space form $SO(3)$. Translations, rotations, boosts, and spacetime transformations form the Galilean, Lorentz, and Poincare groups.

A one-parameter subgroup is a smooth family $g(t)$ satisfying $g(s + t) = g(s)g(t)$. For ordinary rotations, $g(t)$ rotates through angle t . For boosts, hyperbolic functions appear: $\exp(jt) = \cosh t + j \sinh t$ with $j^2 = 1$. For dual numbers, $\exp(\varepsilon t) = 1 + \varepsilon t$ with $\varepsilon^2 = 0$, producing a shear-like motion.

201. Lie algebras and infinitesimal motion.

The tangent vectors at the identity of a Lie group form its Lie algebra. The Lie bracket measures the first-order difference between doing two infinitesimal motions in opposite orders:

$$[X, Y] = XY - YX$$

when the group is represented by matrices. It is bilinear, antisymmetric, and satisfies the Jacobi identity.

The exponential map sends a Lie-algebra element X to a group element $\exp(X)$. Near the identity, the group and algebra contain the same local information. The Baker–Campbell–Hausdorff formula explains how the logarithms of two nearby transformations combine.

202. Lie's three theorems.

Lie's first theorem constructs a basis of infinitesimal transformations. His second theorem expresses the structure constants of

the algebra through commutators. His third theorem says the structure constants are antisymmetric and satisfy the Jacobi identity. The converse results reconstruct a local Lie group from a finite-dimensional Lie algebra under suitable analytic conditions [2].

203. Examples.

The unit quaternions form a three-dimensional group identified with the sphere S^3 . Their Lie algebra is the space of imaginary quaternions, and its bracket is twice the vector cross product. The Heisenberg group consists of upper triangular matrices and is the simplest important noncommutative example. Classical matrix groups such as GL_n , SL_n , O_n , and Sp_n provide the main families.

204. Structure and representations.

Root systems and root data encode the structure of semisimple Lie algebras. Weyl and Coxeter groups describe reflections in roots. Lie groups act on vector spaces through representations, allowing symmetry to be studied with matrices. In physics, representations of rotation and Lorentz groups classify angular momentum and particle types.

Lie theory also includes algebraic groups, groups of Lie type over finite fields, buildings, and the solution of Hilbert's fifth problem, which asks when a locally Euclidean topological group is a Lie group.

205. Applications.

A symmetry of a differential equation can reduce its variables and produce conserved quantities. In mechanics, rotations and translations explain angular momentum and momentum conservation. In relativity, the Lorentz and Poincare groups organize spacetime. In quantum theory, unitary representations describe states and observables. In robotics and control, $SE(3)$ represents position and orientation, while Lie-group integrators preserve the geometry of motion.

206. What the theory depends on and where it is useful.

Lie theory depends on groups, manifolds, calculus, linear algebra, differential equations, and representation theory. It helps Galois

theory as the continuous analogue of root symmetry, helps geometry through homogeneous spaces, and helps physics by encoding transformation laws.

The Lie algebra captures local behavior but may not determine global topology. Distinct groups can share a Lie algebra while differing by discrete quotients. Global questions therefore require covering groups, fundamental groups, and topology.

4. Important theorems and results

- (a) **Lie correspondence.** Connected, simply connected Lie groups correspond to finite-dimensional real Lie algebras up to isomorphism.
- (b) **Exponential map.** One-parameter subgroups are obtained from Lie-algebra elements by exponentiation.
- (c) **Lie's three theorems.** Infinitesimal transformations satisfy the structure and Jacobi identities, and conversely generate local groups.
- (d) **Cartan classification.** Complex semisimple Lie algebras are classified by root systems of types A , B , C , D , and exceptional types.
- (e) **Noether principle.** Continuous symmetries of an action produce conserved quantities in suitable physical systems [3].

5. Applications

Lie groups and Lie algebras encode continuous symmetries at both the global and infinitesimal levels.

- (a) Differential equations
- (b) geometry
- (c) mechanics
- (d) relativity
- (e) quantum physics
- (f) representation theory

(g) and control.

6. Connections

Using existing theories

- (a) Differential geometry supplies smooth manifolds and tangent vectors, while algebra supplies Lie brackets, linear representations, and root systems.
- (b) Differential equations describe one-parameter motions, and topology distinguishes global group behavior from local algebra.

Helping other theories

- (a) Lie theory helps physics describe continuous symmetry, helps differential equations exploit conserved quantities, and helps geometry classify homogeneous spaces.
- (b) Passing between a Lie group and its Lie algebra replaces nonlinear motion by a local linear-algebraic model.

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1.** What is the Lie algebra of a matrix Lie group?
Solution. It is the tangent space at the identity, equipped with the commutator bracket of infinitesimal matrices.
- (b) **Exercise 2.** Why do rotations form a Lie group?
Solution. Rotations compose and have inverses, and their matrices depend smoothly on the angle. The set of rotations is also a smooth manifold.
- (c) **Exercise 3.** What does the Lie bracket measure?

Solution. It measures the first-order failure of two infinitesimal transformations to commute.

- (d) **Exercise 4.** Why can the same Lie algebra correspond to different global groups?

Solution. The algebra describes behavior near the identity. Global topology, such as whether loops close or a covering is taken, is extra information.

- (e) **Exercise 5.** How does Lie theory help solve differential equations?

Solution. A continuous symmetry can reduce the number of variables or produce invariant quantities, turning a difficult equation into a simpler one.

Chapter 50

Matroid theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. Which collections of objects behave like independent vectors in a vector space, even when the objects are edges of a graph or points in a geometry?

Formal

Matroid theory studies combinatorial independence: a system of sets that captures what it means for elements to be independent, dependent, spanning, or minimal. It unifies results from linear algebra, graph theory, and geometry under one language of circuits, bases, and rank.

2. History

Historical development

- (a) Hassler Whitney.

Whitney introduced matroids in 1935 as an abstraction of linear and algebraic independence. He showed that the exchange property underlying bases of a vector space is a purely combinatorial condition that appears in many settings, and he proved the first duality theorem for matroids [1].

(b) **B.L. van der Waerden and Saunders Mac Lane.**

Van der Waerden observed that geometric configurations, such as points and lines in a projective plane, satisfy independence axioms similar to those of a vector space. Mac Lane independently developed a lattice-theoretic characterization of matroids that emphasizes the dependence structure through flats and their meet-semilattice.

(c) **Jack Edmonds and Paul Seymour.**

Edmonds showed in the 1960s and 1970s that matroid structure leads to efficient algorithms: matroid intersection and matroid partition problems are polynomial-time solvable, unlike many graph problems. Seymour's decomposition theorem for regular matroids completed the structure theory of binary matroids and deepened the link between matroids and combinatorial optimization [2].

3. Theory

Core theory

207. Independent sets and bases.

A matroid is a pair $(E, \mathcal{I})$ where E is a finite set and $\mathcal{I}$ is a collection of subsets called independent sets. The axioms require that the empty set is independent, every subset of an independent set is independent, and the augmentation property holds: if A and B are independent and $|A| < |B|$, some element of $B \setminus A$ can be added to A while remaining independent. A maximal independent set is called a basis. Every basis has the same size, called the rank of the matroid [1].

Two familiar examples illustrate the definition. In a vector space, independent sets are linearly independent sets of vectors and bases are vector-space bases. In a graph, take E as the edge set and define

a set of edges to be independent if it contains no cycle; the resulting matroid is called the graphic matroid. Bases of the graphic matroid are spanning forests, and the rank of a set of edges is the number of vertices minus the number of connected components they span.

208. Circuits and closures.

A circuit is a minimal dependent set. In the graphic matroid, circuits are cycles of the graph. In a vector matroid, a circuit is a minimal linearly dependent set of vectors. The circuit elimination axiom says that if C_1 and C_2 are distinct circuits sharing an element e , then $(C_1 \cup C_2) \setminus \{e\}$ contains a circuit.

The closure of a set A , written $\text{cl}(A)$, is the largest set whose rank equals the rank of A . An element in the closure of A but not in A is said to be spanned by A . A flat is a set that equals its own closure. The lattice of flats of a matroid, ordered by inclusion, captures the matroid's geometric structure: flats of rank r in a rank- r matroid are the hyperplanes.

209. Representable matroids.

A matroid is representable over a field F if its elements can be labeled by vectors in a finite-dimensional F -vector space so that independent sets correspond to linearly independent vectors. Every graphic matroid is representable over every field: assign a vector in F^{n-1} (or the cycle space) to each edge. Matroids that are representable over $GF(2)$ are called binary; those representable over every field are called regular. Not all matroids are representable: the smallest non-representable matroid is U_2^4 , the uniform matroid of rank 2 on four elements, which fails over every field [2].

210. Duality and operations.

The dual of a matroid M on ground set E has as its bases the complements of the bases of M . If M is a graphic matroid of a connected graph G , then its dual is the graphic matroid of any planar dual of G . Deletion $M \setminus e$ removes element e ; contraction M/e forces e into every basis. These two operations are the fundamental reductions of matroid theory, much as vertex deletion and edge contraction are in graph theory.

The direct sum of two matroids on disjoint ground sets has as its independent sets the unions of independent sets from each summand.

The restriction $M|A$ of M to a subset $A \subseteq E$ keeps only elements of A . A loop is a circuit of size one; a coloop is an element that belongs to every basis. Deleting a loop does not change the rank; contracting a coloop reduces the rank by one.

211. Matroid intersection and optimization.

Two matroids on the same ground set may ask for a common independent set of maximum size. This matroid intersection problem is solvable in polynomial time by augmenting-path algorithms, generalizing bipartite matching and shortest-path problems. The matroid partition problem, which asks how many matroids are needed to cover a set, is likewise efficiently solvable. These results stand in contrast to NP-hard problems on general independence systems: matroid structure is what makes optimization tractable.

212. Connectivity and structure.

A matroid is connected if it cannot be written as a direct sum of two non-empty matroids. The components of a matroid are its maximal connected restriction and contraction pieces. For a graphic matroid, connectivity of the matroid corresponds to 2-connectedness of the underlying graph. Seymour's decomposition theorem says that every regular matroid can be built from graphic and cographic matroids along certain three-sum operations, giving a complete inductive structure for the regular class [2].

213. Coloring and extensions.

Matroid coloring assigns elements so that no basis is monochromatic. The number of colors needed is related to the girth of the dual. The theory of matroid extensions and minors mirrors the Robertson–Seymour graph minor theory: there is a finite set of forbidden minors for each proper class of matroids, though the list is generally unknown. The Robertson–Seymour theorem for graph minors is a special case: graphs are exactly the graphic and cographic matroids plus one extra class, and the minor-closed property gives structural consequences.

214. Applications.

In combinatorial optimization, the greedy algorithm finds a maximum-weight basis of a matroid in polynomial time, which is why minimum spanning trees can be found by sorting edges and

adding them greedily. Network design problems such as finding minimum-cost spanning structures are modelled by matroids. In coding theory, the bases of a matroid correspond to generating sets, and matroid duality translates into code duality. The Tutte polynomial of a matroid generalizes the chromatic polynomial of a graph and the Jones polynomial of a knot, unifying enumerative invariants across combinatorics [3].

215. What the theory depends on and where it is useful.

Matroid theory depends on sets, linear algebra, graph theory, and combinatorics. It helps combinatorial optimization provide efficient algorithms, helps graph theory generalize cycle and spanning-tree arguments, helps coding theory unify code constructions, and helps geometry study configurations of points and flats. Its abstraction strips away metric and algebraic detail, leaving only independence structure; the cost is that some problems gain structure but not computation speed when the matroid is not representable [1].

4. Important theorems and results

- (a) **Basis exchange axiom.** If B_1 and B_2 are bases of a matroid and $e \in B_1 \setminus B_2$, then there exists $f \in B_2 \setminus B_1$ such that $(B_1 \setminus \{e\}) \cup \{f\}$ is a basis.
- (b) **Circuit elimination.** If C_1 and C_2 are distinct circuits sharing an element e , then $(C_1 \cup C_2) \setminus \{e\}$ contains a circuit.
- (c) **Duality.** The dual of a matroid is a matroid. If M has rank r on ground set E , then M^* has rank $|E| - r$, and the bases of M^* are the complements of the bases of M .
- (d) **Matroid intersection theorem.** For two matroids M_1 and M_2 on the same ground set, the maximum size of a common independent set equals the minimum of $r_1(X) + r_2(E \setminus X)$ over all subsets $X \subseteq E$, where r_i is the rank function of M_i .
- (e) **Seymour's decomposition theorem.** Every regular matroid can be constructed from graphic and cographic matroids along 3-sums, and conversely every such construction is regular [2].

5. Applications

Bases, circuits, independence, and rank describe when elements can or cannot replace one another without losing structural freedom.

- (a) Combinatorial optimization
- (b) graph theory
- (c) coding theory
- (d) network design
- (e) algorithm design
- (f) and geometry.

6. Connections

Using existing theories

- (a) Linear algebra supplies the representable case with vector spaces, independence, and rank; graph theory supplies graphic matroids via cycles and forests; combinatorics supplies counting and extremal arguments.
- (b) Algorithms turn independence and exchange properties into greedy, intersection, and partition procedures with guaranteed optimality.

Helping other theories

- (a) Matroid theory helps combinatorial optimization, coding theory, network design, scheduling, and the study of geometric configurations.
- (b) By abstracting independence from algebra and graph theory, it provides a unified language for when elements can be added, removed, or exchanged without losing structure.

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1.** Identify the bases and circuits of the graphic matroid of K_4 .

Solution. The ground set is the six edges of K_4 . A basis is any spanning tree of K_4 , which has three edges. A circuit is any cycle, such as a triangle, which has three edges.

- (b) **Exercise 2.** Is every graphic matroid representable?

Solution. Yes. Every graphic matroid is representable over every field by assigning vectors to edges in the cycle space of the graph.

- (c) **Exercise 3.** If M has rank 4 on a ground set of size 8, what is the rank of its dual M^* ?

Solution. The dual has rank $|E| - \text{rank}(M) = 8 - 4 = 4$.

- (d) **Exercise 4.** Give an example of a matroid that is not representable over any field.

Solution. The uniform matroid U_2^4 of rank 2 on four elements has no representation over any field; its four-element ground set of rank 2 has no three-element circuit but cannot be embedded in any vector space with the required independence properties.

- (e) **Exercise 5.** What does the greedy algorithm find on a matroid?

Solution. Given weights on the elements, the greedy algorithm finds a maximum-weight basis. For a graphic matroid, this is a minimum-weight spanning tree.

Chapter 51

M-theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. Can the apparently different superstring theories be different descriptions of one deeper theory that includes quantum gravity?

Formal

M-theory is a proposed eleven-dimensional framework whose low-energy limit is eleven-dimensional supergravity and whose objects include strings, membranes, and five-branes. It is not yet known in one complete formulation.

2. History

Historical development

(a) **Edward Witten.**

Witten used strong–weak dualities to argue that the five consistent superstring theories are different limits of a deeper theory, which he called M-theory. The proposal connected

type IIA string theory at strong coupling with an additional eleven-dimensional direction.

(b) **Michael Duff, Paul Townsend, and duality researchers.**

Their work on membranes, branes, and duality relations supplied the eleven-dimensional supergravity and compactification evidence used to test the M-theory picture. These results support the framework, but they do not constitute a complete nonperturbative definition [1, 2].

3. Theory

Core theory

216. The problem it addresses.

General relativity describes gravity and spacetime smoothly. Quantum mechanics describes nongravitational matter through probabilities and operators. Applying the usual quantum rules to gravity produces serious infinities and conceptual difficulties. String theory replaces point particles by vibrating one-dimensional strings; one vibration behaves like a graviton, the quantum carrier of gravity [1].

In 1995 Edward Witten proposed that the five consistent superstring theories are limiting descriptions of one theory. His proposal began the second superstring revolution. The letter M has deliberately been associated with membrane, magic, or mystery; its final interpretation awaits a more fundamental formulation.

217. Concrete illustration: why one theory instead of five.

A useful analogy is a mountain seen from different valleys. From the north valley the mountain looks steep and jagged; from the south it looks gentle and rounded. An observer in each valley might believe they are studying different mountains. The five superstring theories—type I, type IIA, type IIB, heterotic $SO(32)$, and heterotic $E_8 \times E_8$ —are like five valleys. Each theory looks different because it is analyzed in a particular perturbative regime with its own expansion parameter. Dualities are the mountain trails connecting them: T-duality links a string on a circle of radius R to one on a circle of radius ℓ_s^2/R , so that large and small radii are physically

equivalent; S-duality links a theory at strong coupling to another at weak coupling. Once all the trails are traced, one finds that the five valleys belong to a single landscape—M-theory—whose eleven-dimensional low-energy limit is supergravity.

218. Why eleven dimensions appear.

The five perturbative string theories are type I, type IIA, type IIB, and the two heterotic theories with gauge groups related to $SO(32)$ and $E_8 \times E_8$. They appear different because they use different perturbative expansions and include different kinds of strings.

Dualities relate apparently different descriptions. T-duality exchanges a theory compactified on a circle of radius R with another on a circle of radius proportional to $1/R$. S-duality exchanges strong and weak coupling. Type IIA at strong coupling develops an additional spatial dimension and approaches eleven-dimensional supergravity. The web of dualities suggests that the five theories are limits of M-theory [2].

219. Branes and low-energy supergravity.

M-theory should contain two-dimensional membranes, called M2-branes, and five-dimensional M5-branes, in addition to string-like objects that appear after compactification. At low energies, where the detailed string scale is invisible, the theory is approximated by eleven-dimensional supergravity.

Compactification hides extra dimensions. If seven dimensions are wrapped on a small compact space, observers at long distances see an apparently four-dimensional theory. Compactifying on manifolds with special holonomy, such as G_2 manifolds, can produce supersymmetric four-dimensional models. Heterotic M-theory uses eleven-dimensional geometry with boundaries to relate M-theory to the $E_8 \times E_8$ heterotic string.

220. History before Witten.

Kaluza–Klein theory had already proposed an extra compact dimension to unite gravity and electromagnetism. Early supergravity supplied a field theory with local supersymmetry. Work on membranes and five-branes and the web of relationships among string theories prepared the setting for Witten’s unification proposal.

221. Matrix theory.

The BFSS matrix model proposes that M-theory in a particular infinite-momentum limit is described by quantum mechanics of large matrices. Matrix entries represent collective degrees of freedom, and diagonal configurations can be interpreted as positions of D-branes. Noncommutative geometry appears because matrix coordinates need not commute.

Matrix theory is valuable because it gives a concrete definition in a special limit, although connecting it to the full theory in all backgrounds remains difficult. It has provided tests of dualities, calculations of black-hole behavior, and links between geometry and large matrices [3].

222. **AdS/CFT correspondence.**

The AdS/CFT correspondence proposes an equivalence between a gravitational theory in an anti-de Sitter bulk and a conformal field theory on its boundary. The six-dimensional $(2,0)$ superconformal field theory and the three-dimensional ABJM theory provide important examples related to M2 and M5 branes.

The correspondence changes a hard quantum-gravity calculation into a boundary field-theory calculation and vice versa. It is a conjectural duality, not merely an analogy, but its complete mathematical proof is unknown. It has influenced quantum information, condensed matter, geometry, and the study of strongly coupled field theories.

223. **Phenomenology and present status.**

Phenomenological work seeks compactifications whose low-energy spectrum resembles the Standard Model. G_2 compactifications and heterotic M-theory are prominent approaches. The extra dimensions must be stabilized, supersymmetry may be broken, and the resulting masses and couplings must agree with experiments.

No compactification of M-theory has been experimentally confirmed. The theory is therefore a research framework with powerful mathematical consequences, not an established description of observed physics [4].

224. **What the theory depends on and where it is useful.**

M-theory depends on quantum mechanics, general relativity, quantum field theory, supersymmetry, differential geometry, topology,

and string theory. It helps study quantum gravity, black holes, gauge theories, dualities, and strongly coupled systems.

4. Important theorems and results

- (a) **Duality web.** T-duality and S-duality relate the five superstring descriptions and motivate a single underlying theory.
- (b) **Eleven-dimensional supergravity limit.** At low energies M-theory is approximated by eleven-dimensional supergravity.
- (c) **Brane content.** M2- and M5-branes are central extended objects in the proposed theory.
- (d) **BFSS conjecture.** A large-matrix quantum-mechanical model gives M-theory in an infinite-momentum limit.
- (e) **AdS/CFT conjecture.** Certain bulk gravitational theories are dual to boundary conformal field theories [3].

The first three statements describe the proposed framework and its low-energy objects; they are not a complete definition of M-theory. BFSS and AdS/CFT are conjectural dual descriptions that offer testable consequences in special limits. Their value is therefore methodological: difficult quantum-gravity questions may be translated into matrix or field-theory calculations, while the lack of a complete formulation remains an explicit limitation.

5. Applications

Dualities, branes, and higher-dimensional limits relate apparently different quantum-gravitational descriptions.

- (a) Quantum gravity
- (b) string dualities
- (c) black holes
- (d) gauge theory
- (e) cosmology
- (f) matrix models

- (g) and mathematical physics.

6. Connections

Using existing theories

- (a) Differential geometry supplies manifolds and curvature, quantum field theory supplies fields and supersymmetry, and string theory supplies dualities and branes.
- (b) Algebraic topology and representation theory organize the charges and dimensions that appear in the proposed models.

Helping other theories

- (a) M-theory helps mathematical physics compare apparently different string theories and motivates geometric structures such as special holonomy.
- (b) Its applications are conjectural in places, so a physical analogy must be distinguished from a proved mathematical result.
- (c) **Black hole entropy calculations.** The Bekenstein–Hawking entropy of a black hole is proportional to its event-horizon area. In string theory, certain black holes can be constructed from intersecting D-branes whose low-energy dynamics is governed by a supersymmetric gauge theory. Counting the microstates of this gauge theory reproduces the Bekenstein–Hawking entropy formula exactly. In the M-theory context, black holes in five dimensions (with $AdS_3 \times S^2$ near-horizon geometry) are dual to two-dimensional conformal field theories whose central charge is computed from M2-brane configurations, giving a microscopic derivation of the entropy—a concrete instance where M-theory produces a testable, quantitative prediction.
- (d) **Holographic principle and AdS/CFT.** The holographic principle states that the information content of a region of space is encoded on its boundary. M-theory provides the sharpest realization through the AdS/CFT correspondence: a gravitational theory in $(d + 1)$ -dimensional anti-de Sitter space is exactly equivalent to a conformal field theory on its

d -dimensional boundary. This has become a practical computational tool in nuclear physics (modeling the quark–gluon plasma at RHIC and the LHC), in condensed-matter physics (holographic superconductors), and in quantum information (entanglement entropy and the “it from qubit” program).

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1.** Why does string theory help with quantum gravity?

Solution. A string has a finite extent rather than being a point. Its quantum vibrational spectrum includes a graviton, and interactions can be softer at very short distances.

- (b) **Exercise 2.** What does compactification do?

Solution. It wraps extra dimensions into a small compact space. At accessible distances the hidden directions are not resolved, so the effective theory has fewer dimensions.

- (c) **Exercise 3.** What is a duality?

Solution. It is an equivalence between two descriptions that look different in variables or regimes but produce the same physical content.

- (d) **Exercise 4.** Why are membranes important?

Solution. M-theory is not limited to one-dimensional strings. M2- and M5-branes provide higher-dimensional objects whose compactifications and interactions generate string and field-theory descriptions.

- (e) **Exercise 5.** Has M-theory been experimentally verified?

Solution. No. It has strong internal mathematical relationships and useful limiting descriptions, but no compactification has been confirmed as the observed universe.

Chapter 52

Measure theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How can length, area, probability, and size be defined consistently for complicated sets?

Formal

Measure theory assigns a nonnegative size to a carefully chosen family of sets and extends finite addition to countably many disjoint pieces. It provides the foundation for modern integration and probability.

2. History

Historical development

(a) **Émile Borel and Henri Lebesgue.**

Borel identified useful classes of measurable sets, and Lebesgue constructed an integral that remains stable under limits and handles irregular sets. Their work replaced ad hoc notions of area with countably additive measure and rigorous integration.

(b) Constantin Carathéodory and Andrey Kolmogorov.

Carathéodory's outer-measure construction gave a systematic route to measurable sets. Kolmogorov built modern probability on measure spaces, making measure theory the common language for integration, probability, and ergodic theory [1].

3. Theory**Core theory****225. Why ordinary length is not enough.**

Intervals have length, rectangles have area, and boxes have volume. But limits, fractal sets, and irregular regions are not always built from finitely many such pieces. Measure theory replaces a ruler with rules that survive countable approximation. It was developed through the work of Borel, Lebesgue, Carathéodory, and later Kolmogorov [1].

A measure space consists of a set X , a sigma-algebra Σ of measurable subsets, and a measure μ satisfying $\mu(\emptyset) = 0$ and countable additivity:

$$\mu\left(\bigcup_{n=1}^{\infty} E_n\right) = \sum_{n=1}^{\infty} \mu(E_n)$$

for pairwise disjoint measurable sets. The sigma-algebra is closed under complements and countable unions, ensuring that the operations used in limits remain measurable.

226. Lebesgue measure.

Lebesgue measure agrees with ordinary length on intervals: $\mu([a, b]) = b - a$. It extends this to a large family of subsets of the real line and higher-dimensional Euclidean space. A set of measure zero may be nonempty, such as a point or the Cantor set, and changing a function on such a set does not change its integral.

The outer-measure construction begins by covering a set with intervals or boxes and taking the infimum of the total lengths or volumes. Carathéodory's criterion selects the measurable sets for which every set splits cleanly with respect to outer measure. This construction explains why some subsets of the real line cannot be

assigned a translation-invariant countably additive length without additional assumptions.

227. Integration.

The Lebesgue integral first integrates indicator functions, then non-negative simple functions, and finally general measurable functions by approximation. It can integrate functions with infinitely many discontinuities when the total contribution is controlled. The spaces L^p identify functions that differ only on a null set and use

$$\|f\|_p = \left(\int |f|^p d\mu \right)^{1/p}.$$

Lebesgue integration is the natural language for limits of random variables and solutions of PDEs.

228. Convergence theorems.

The monotone convergence theorem permits increasing nonnegative approximations to pass through the integral. Fatou's lemma gives a one-sided inequality for lower limits. The dominated convergence theorem permits pointwise convergence under an integrable dominating function:

$$f_n \rightarrow f, \quad |f_n| \leq g, \quad \int g < \infty \quad \implies \quad \int f_n \rightarrow \int f.$$

These theorems justify exchanging limits and integrals, which is often the decisive step in analysis.

229. Probability and product spaces.

Probability is a measure with $\mu(X) = 1$. A random variable is a measurable function, and expectation is its Lebesgue integral. Independence is expressed through product measures. Fubini's theorem integrates over a product in either order when absolute integrability holds; Tonelli's theorem gives the corresponding result for nonnegative functions.

Pushforward measure transports a measure through a measurable map. Conditional expectation is the best measurable average given partial information and is the foundation of martingales and modern probability.

230. Regularity, completeness, and generalizations.

A complete measure includes every subset of every null set. Regular measures approximate measurable sets from inside by compact sets and from outside by open sets. Signed measures allow cancellation; complex and vector measures support harmonic analysis. Hausdorff measure extends length and area to fractals, while geometric measure theory studies rectifiable sets and minimal surfaces.

Finitely additive contents and charges relax countable additivity and connect to Banach limits and the Stone–Cech compactification, but countable additivity is what makes convergence theorems work [2].

231. What the theory depends on and where it is useful.

Measure theory depends on set theory, real analysis, topology, and probability. It helps ergodic theory define invariant averages, distribution theory define weak objects, operator theory build L^p spaces, and geometry measure irregular shapes.

Not every subset is measurable, and an integral depends on the chosen measure. A probability model is useful only when its sample space and measure correspond to the experiment.

4. Important theorems and results

- (a) **Carathéodory extension theorem.** A suitable premeasure on simple sets extends to a measure on the generated sigma-algebra.
- (b) **Monotone convergence theorem.** Integrals commute with increasing limits of nonnegative measurable functions.
- (c) **Dominated convergence theorem.** An integrable bound permits integration after pointwise convergence.
- (d) **Fubini–Tonelli theorem.** Under the appropriate nonnegative or integrability hypotheses, product integrals can be computed as iterated integrals.
- (e) **Radon–Nikodym theorem.** A measure absolutely continuous with respect to another has a density, generalizing the derivative of one measure with respect to another [3].

5. Applications

Measurable sets, countable additivity, and integration provide a rigorous way to aggregate quantities over irregular or infinite domains.

- (a) Probability
- (b) analysis
- (c) ergodic theory
- (d) PDEs
- (e) geometry
- (f) economics
- (g) statistics
- (h) and mathematical physics.

6. Connections

Using existing theories

- (a) Set theory supplies sigma-algebras, real analysis supplies limits and integration, and topology supplies regularity and approximation by open and compact sets.
- (b) Probability is the normalized case, while functional analysis uses measurable functions as elements of L^p spaces.

Helping other theories

- (a) Measure theory helps probability, PDEs, harmonic analysis, ergodic theory, and geometric measure theory define size and integration beyond finite sums.
- (b) Its convergence theorems justify exchanging limits, sums, derivatives, and integrals when the stated hypotheses hold.

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1.** Why is countable additivity stronger than ordinary finite additivity?

Solution. It controls an infinite disjoint decomposition. This is essential when a set or function is approximated by a sequence of simpler pieces.

- (b) **Exercise 2.** What does measure zero mean?

Solution. The set contributes no size to the measure, although it need not be empty. A function can be changed on a null set without changing its Lebesgue integral.

- (c) **Exercise 3.** When can limits pass through an integral?

Solution. Monotone or dominated convergence gives standard sufficient conditions. Without such control, pointwise convergence alone is not enough.

- (d) **Exercise 4.** Why is a random variable required to be measurable?

Solution. Measurability ensures inverse images of measurable outcome sets are measurable, so probabilities and expectations are defined.

- (e) **Exercise 5.** What is the Radon–Nikodym theorem used for?

Solution. It represents an absolutely continuous measure by a density, allowing one measure to be integrated relative to another.

Chapter 53

Model theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. What is the relationship between a formal description and the mathematical structures in which it is true?

Formal

Model theory studies languages, theories, structures, and definable sets. It asks which statements have models, how large those models can be, and how models compare.

2. History

Historical development

(a) **The basic idea and history.**

A formal language has symbols for functions, relations, and constants. A theory is a collection of sentences written in that language. A model is a structure in which every sentence of

the theory is true. The integers, real numbers, groups, fields, and graphs can all be models of suitable theories [1].

Alfred Tarski coined the term "theory of models" in 1954. Earlier work by Lowenheim, Skolem, Godel, and Malcev supplied the compactness and completeness tools. Since the 1970s, Saharon Shelah's stability theory has shaped the subject.

3. Theory

Core theory

232. Structures and formulas.

The language of rings has symbols $+$, $\times$, $-$, 0 , and 1 . In a field, the formula $y = x \times x$ defines the parabola $y = x^2$. A formula with free variables defines a set; a sentence with no free variables is either true or false in a structure.

Definable sets can use parameters from the model. Over the real numbers, $y = x^2 + \pi$ is definable using π . Model theory studies not only the objects named by a theory but also which subsets can be described in its language.

233. Completeness, compactness, and size.

The completeness theorem says that a first-order sentence is true in every model of a theory exactly when it has a formal proof from that theory. The compactness theorem says that if every finite subset of a set of first-order sentences has a model, then the whole set has a model.

The downward Lowenheim–Skolem theorem says that a theory with an infinite model has models of many smaller infinite cardinalities, down to the size of its language. The upward theorem gives models in arbitrarily large cardinalities. Thus first-order axioms often cannot uniquely specify the size of an infinite structure.

234. Quantifier elimination.

Quantifiers such as "there exists" can hide the shape of a definable set. A theory has quantifier elimination if every formula is equivalent to one without quantifiers. Algebraically closed fields have quantifier

elimination in the language of rings: every definable set is a Boolean combination of polynomial equations.

The theory of real closed fields also has quantifier elimination after adding an order relation. This yields the decidability of many elementary geometric questions and is the logical basis of cylindrical algebraic decomposition. Model completeness is a weaker property in which embeddings between models preserve all formulas in an appropriate sense [2].

235. Ultraproducts and nonstandard analysis.

An ultraproduct combines a family of structures while ignoring a chosen collection of exceptional indices. Los's theorem says a first-order sentence holds in the ultraproduct exactly when it holds in almost all components according to the ultrafilter. Ultraproducts compare finite structures with infinite limits and help prove transfer principles.

Robinson used these ideas to build nonstandard analysis, where infinitesimal and infinitely large numbers are handled rigorously. Ax's work on pseudofinite fields and the Ax–Kochen theorem are important applications of ultraproduct methods.

236. Stability, o-minimality, and definable geometry.

Stability theory classifies theories by how complicated their definable sets and types can be. Stable, simple, NIP, and distal theories form part of a hierarchy. Geometric stability theory applies these ideas to algebraic and diophantine geometry.

O-minimal structures are ordered structures in which every definable subset of the line is a finite union of points and intervals. This tame one-dimensional behavior controls higher-dimensional definable geometry. Pila and others used o-minimal methods in problems related to the Andre–Oort conjecture. Hrushovski used model-theoretic geometry in the Mordell–Lang and Manin–Mumford settings [3].

237. Applications.

Finite model theory studies finite structures and is central to database queries, descriptive complexity, and graph properties. A query is definable by a logical formula, and the expressive power of the logic can be compared with computational complexity classes.

Model theory also studies real algebraic geometry, differential fields, valued fields, p -adic fields, number fields, and pseudofinite fields. NIP theories and stability have connections to PAC learning and online learning classes. The theory is useful when algebraic structure and logical definability must be analyzed together.

238. What the theory depends on and where it is useful.

Model theory depends on first-order logic, set theory, algebra, and combinatorics. It helps algebra by transferring statements between models, geometry by describing definable sets, number theory by analyzing fields, and computer science by comparing logical descriptions with algorithms.

First-order logic cannot express every mathematical property, and a complete theory may have nonisomorphic models of different sizes. These are not failures; they identify exactly what the chosen language and axioms can control.

4. Important theorems and results

- (a) **Godel completeness theorem.** Semantic consequence in first-order logic equals formal provability.
- (b) **Compactness theorem.** If every finite part of a first-order theory is satisfiable, the entire theory is satisfiable.
- (c) **Lowenheim–Skolem theorems.** Infinite first-order theories have models in controlled smaller and larger cardinalities.
- (d) **Los’s theorem.** First-order formulas in an ultraproduct are evaluated componentwise according to the ultrafilter.
- (e) **Tarski quantifier elimination.** Real closed fields admit quantifier elimination in the language of ordered rings [1].

5. Applications

Structures, formulas, and interpretations determine which properties are expressible and how algebraic models can be compared.

- (a) Mathematical logic

- (b) algebra
- (c) number theory
- (d) geometry
- (e) database theory
- (f) computability
- (g) and learning theory.

6. Connections

Using existing theories

- (a) Logic supplies formulas and satisfaction, set theory supplies structures, and algebra supplies the groups, rings, and fields used as examples.
- (b) Compactness and ultraproducts connect syntax with global and asymptotic properties of structures.

Helping other theories

- (a) Model theory helps algebra by transferring first-order statements between structures and helps computer science analyze formal languages and verification.
- (b) It also studies which properties can be expressed and decided, separating definability from computation.

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1.** What is a model of a group theory?

Solution. It is a set equipped with an operation, identity, and inverse operation satisfying every group axiom. The integers under addition are one model.

- (b) **Exercise 2.** What does compactness say in practical language?

Solution. If no finite collection of requirements creates a contradiction, then all requirements can be satisfied together in some model.

- (c) **Exercise 3.** What is a definable set?

Solution. It is a set of tuples described by a formula, possibly using fixed parameters from the structure.

- (d) **Exercise 4.** Why is quantifier elimination useful?

Solution. It replaces hidden existential and universal searches by simpler equations and inequalities, making definable sets easier to describe and decide.

- (e) **Exercise 5.** Why can a theory have models of different sizes?

Solution. First-order sentences describe finite patterns and relations but generally cannot say that an infinite model has exactly one particular infinite cardinality.

Chapter 54

Module theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. What remains true about linear algebra when scalars come from a ring instead of a field?

Formal

A module is an abelian group on which a ring acts like scalars. Modules generalize vector spaces and abelian groups, but can have torsion, relations, and no basis.

2. History

Historical development

(a) **Emmy Noether.**

Noether developed the chain-condition methods that organize finitely generated modules and ideals. Her structural viewpoint made it possible to study algebra through generators, relations, and maps rather than through coordinates alone.

- (b) **Emil Artin, Saunders Mac Lane, and homological algebraists.**

The structure theorem over principal ideal domains classified important modules, while homological algebra organized modules through exact sequences, derived functors, and resolutions. These developments made modules central to representation theory, algebraic geometry, and topology [1].

3. Theory

Core theory

239. The problem and definition.

Vector spaces allow addition and multiplication by scalars from a field. Many natural coefficient systems are rings instead: integers, polynomial rings, or smooth functions. A module over a ring R is an additive abelian group M with scalar multiplication satisfying distributivity, associativity with ring multiplication, and the identity rule. Every abelian group is a $\mathbb{Z}$ -module, and every vector space is a module over its field [1].

The difference is important. In a vector space, every nonzero scalar is invertible and bases behave uniformly. In a module, $2m$ may be zero for nonzero m , and a generating set may have relations.

240. Examples.

The ring R is a module over itself, and R^n is a free module. The integers $\mathbb{Z}/n\mathbb{Z}$ are $\mathbb{Z}$ -modules with torsion. Ideals are submodules of a ring. Quotient rings are quotient modules.

If X is a smooth manifold, smooth functions $C^\infty(X)$ form a ring. Smooth vector fields, differential forms, and tensor fields form modules over this ring. Sections of a vector bundle form projective modules; Swan's theorem says that over suitable compact spaces projective modules correspond to vector bundles.

241. Submodules, maps, and quotients.

A submodule is an additive subgroup closed under multiplication by ring elements. A module homomorphism preserves addition and

scalar multiplication. Its kernel is a submodule, and the quotient by the kernel is isomorphic to its image.

The submodule generated by a set consists of finite sums $\sum r_i x_i$. A module is finitely generated when a finite set generates it, finitely presented when finitely many generators and relations describe it, and free when it has a basis. Projective modules behave like direct summands of free modules; injective modules provide extension properties.

242. Structure and relations.

Over a principal ideal domain, finitely generated modules split into a free part and cyclic torsion parts. The integer case is the structure theorem for finitely generated abelian groups:

$$M \cong \mathbb{Z}^r \oplus \mathbb{Z}/d_1 \oplus \cdots \oplus \mathbb{Z}/d_k,$$

with divisibility conditions on the d_i . Over arbitrary rings this simple classification fails, so one uses exact sequences, resolutions, localization, and invariants such as rank and depth.

Modules over matrix rings are equivalent in category to modules over the original ring in the Morita theory. A Lie-algebra module is a module over its universal enveloping algebra. Representations of groups are modules over group algebras.

243. Homological algebra and geometry.

A projective or free resolution replaces a complicated module by a chain of simple modules. Applying Hom or tensor product to a resolution produces Ext and Tor, which measure failure of exactness. This is the algebra behind derived functors and sheaf cohomology.

In algebraic geometry, a sheaf of modules records functions or sections locally on open sets. Coherent modules over a coordinate ring describe algebraic vector bundles, ideals, and singularities. Localization studies a module near a prime ideal, while completion studies its formal neighborhood [2].

244. What the theory depends on and where it is useful.

Module theory depends on rings, groups, linear algebra, and exact sequences. It helps representation theory turn actions into modules, algebraic geometry encode sheaves, topology calculate homology, and K-theory classify projective modules.

4. Important theorems and results

- (a) **Structure theorem over a PID.** Finitely generated modules decompose into free and cyclic torsion parts.
- (b) **First isomorphism theorem.** A module modulo the kernel of a homomorphism is isomorphic to its image.
- (c) **Nakayama's lemma.** Over a local ring, generators modulo the maximal ideal lift to generators of a finitely generated module.
- (d) **Hilbert syzygy theorem.** Polynomial rings over a field have finite projective resolutions of bounded length.
- (e) **Swan's theorem.** Suitable finitely generated projective modules over continuous functions are exactly vector-bundle sections [3].

5. Applications

Modules generalize vector spaces over rings, so generators, relations, maps, and exact sequences describe algebra beyond fields.

- (a) Commutative algebra
- (b) representation theory
- (c) homological algebra
- (d) algebraic geometry
- (e) topology
- (f) and differential geometry.

6. Connections

Using existing theories

- (a) Linear algebra supplies vector spaces as the simplest modules, while ring theory supplies scalar multiplication and ideals.

- (b) Homological algebra studies exact sequences and resolutions, and algebraic geometry interprets modules as sheaves or sections.

Helping other theories

- (a) Module theory helps classify algebraic objects, solve systems over rings, and compute invariants such as Ext and Tor.
- (b) It also provides the language for representations, coherent sheaves, and finitely generated data in algebraic geometry.

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1.** Why is every abelian group a module over $\mathbb{Z}$?
Solution. Define ng as repeated addition for positive n , its inverse for negative n , and $0g = 0$. The module laws follow from group laws.
- (b) **Exercise 2.** Is $\mathbb{Z}/6\mathbb{Z}$ a free $\mathbb{Z}$ -module?
Solution. No. The nonzero class 1 is killed by 6, so it has torsion. A free $\mathbb{Z}$ -module has no nonzero torsion.
- (c) **Exercise 3.** What does a module presentation record?
Solution. It records generators and the equations or relations among them. It is a compact description of how the module is built.
- (d) **Exercise 4.** Why are projective modules called vector-bundle-like?
Solution. They are direct summands of free modules, just as vector bundles may be embedded as summands of trivial bundles.
- (e) **Exercise 5.** What does localization do to a module?
Solution. It makes selected ring elements invertible and focuses the module on behavior near a prime or region of the spectrum.

Chapter 55

Morse theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How can the critical points of an ordinary height function reveal the topology of a manifold?

Formal

Morse theory studies smooth functions whose critical points are nondegenerate. As a level rises, the manifold changes only when it passes a critical point, and each critical point attaches a cell or handle.

2. History

Historical development

(a) **History and the landscape picture.**

Imagine a mountain landscape. At most heights, contour lines change smoothly. At a valley a new component appears; at a saddle two contours join or split; at a peak a component disappears. Marston Morse made this picture precise. Earlier

topographical ideas came from Cayley and Maxwell, and Morse first applied the method to geodesics and energy functionals [1].

A smooth function $f : M \rightarrow \mathbb{R}$ has a critical point where its derivative is zero. It is nondegenerate when the Hessian has no zero eigenvalue. The number of negative Hessian directions is the Morse index. A Morse function has only nondegenerate critical points, and a small generic perturbation usually makes a function Morse.

3. Theory

Core theory

245. The Morse lemma.

Near a critical point of index λ , suitable coordinates make

$$f = f(p) - x_1^2 - \cdots - x_\lambda^2 + x_{\lambda+1}^2 + \cdots + x_n^2.$$

Thus every nondegenerate critical point looks locally like a standard quadratic saddle. Below the critical value the sublevel set $M_a = \{x : f(x) \leq a\}$ changes only by attaching a λ -dimensional cell when the level crosses the critical point.

246. Topology from critical points.

Climbing the function builds a CW structure on M . One cell of dimension λ appears for each critical point of index λ . Consequently the number C_λ of such critical points is at least the Betti number b_λ . The alternating sum gives

$$\chi(M) = \sum_{\lambda} (-1)^\lambda C_\lambda.$$

Morse inequalities strengthen this to bounds on alternating sums of critical-point counts. A sphere can be built from one minimum and one maximum; a torus needs a minimum, two saddles, and a maximum.

247. Closed surfaces and handles.

On a compact surface, the index-zero critical points add disks, index-one points add bands, and index-two points cap off the surface.

Counting them distinguishes the sphere, torus, and higher-genus surfaces. Handle decompositions in higher dimensions are the manifold version of the same construction.

Morse homology forms a chain complex generated by critical points, with differential counting gradient-flow lines between points whose indices differ by one. Its homology is isomorphic to singular homology, so analysis of a gradient field computes topological holes.

248. Morse–Bott theory and other applications.

Morse–Bott theory permits the critical set to be a smooth submanifold rather than isolated points, while requiring a nondegenerate Hessian in normal directions. This is useful when symmetry forces critical points to occur in families.

Morse theory analyzes geodesics as critical points of the energy on path spaces and was used in Bott’s proof of periodicity. In optimization, minima, maxima, and saddles describe landscapes; in physics, energy functions and instantons produce similar cell attachments. The complex analogue is Picard–Lefschetz theory [2].

249. What the theory depends on and where it is useful.

Morse theory depends on calculus, differential topology, manifolds, flows, and homology. It helps handle and cobordism theory construct manifolds, Hodge theory study energy minimizers, and dynamics understand gradient trajectories.

The method requires smoothness and nondegenerate critical points. Critical-point counts give bounds and decompositions, but two different functions on the same manifold may produce very different numbers of critical points.

4. Important theorems and results

- (a) **Morse lemma.** Every nondegenerate critical point has a standard quadratic normal form.
- (b) **Morse inequalities.** Critical points of each index bound the corresponding Betti numbers and satisfy alternating inequalities.

- (c) **Handle decomposition theorem.** A compact smooth manifold admits a handle decomposition associated with a Morse function.
- (d) **Morse homology theorem.** The homology of the Morse complex agrees with singular homology.
- (e) **Morse–Bott generalization.** Nondegenerate critical submanifolds replace isolated critical points [3].

Together these results convert a smooth function into a topological construction. The Morse lemma gives local quadratic coordinates, the inequalities compare critical points with holes, and handle decomposition explains how the manifold is assembled. Morse homology is important because it produces the same invariant as singular homology from gradient trajectories, while the Morse–Bott version shows how the method survives when critical points occur in families.

5. Applications

Critical points, Hessian indices, and gradient flows convert local differential information into a global cell or handle decomposition.

- (a) Differential topology
- (b) homology
- (c) geodesics
- (d) dynamical systems
- (e) optimization
- (f) and mathematical physics.

6. Connections

Using existing theories

- (a) Differential calculus supplies critical points and Hessians, differential topology supplies smooth manifolds, and algebraic topology supplies homology and Betti numbers.

- (b) Gradient flows and handle decompositions connect local derivatives with global shape.

Helping other theories

- (a) Morse theory helps compute the topology of manifolds from critical points and supports optimization, geometry, and dynamical systems.
- (b) Its inequalities give reliable information even when the full manifold or all of its critical points is difficult to describe.

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1.** What is the Morse index of a local minimum?
Solution. Zero, because the Hessian is positive definite and has no negative direction.
- (b) **Exercise 2.** What does an index-one critical point do to a surface?
Solution. It attaches a one-dimensional handle or band. In a landscape it is a saddle where contour components join or split.
- (c) **Exercise 3.** How many critical points can a height function on a sphere have in the simplest Morse picture?
Solution. One minimum and one maximum, of indices zero and two. Their alternating sum is $1+1 = 2$, the Euler characteristic of the sphere.
- (d) **Exercise 4.** Why do Morse inequalities imply topological information?
Solution. Homology ranks count holes, and each homology generator requires enough cells. Critical points create those cells, so their number bounds the holes.

(e) **Exercise 5.** Why is Morse–Bott theory needed?

Solution. Symmetry may make an entire circle or submanifold critical. Morse–Bott theory handles the family while retaining nondegeneracy transverse to it.

Chapter 56

Nevanlinna theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How often does a meromorphic function take a value, and how quickly does it grow as the complex plane expands?

Formal

Nevanlinna theory measures the growth of meromorphic functions and balances value distribution against exceptional values. It is a complex-analytic analogue of counting roots of a polynomial.

2. History

Historical development

(a) **Rolf Nevanlinna.**

Nevanlinna developed the theory in 1925 to measure how often a meromorphic function takes a value as the radius of the disk grows. His counting and proximity functions compare

zeros and poles with the function's total growth, turning value distribution into quantitative inequalities.

- (b) **Lars Ahlfors, André Bloch, Henri Cartan, and later contributors.**

They extended value-distribution methods from meromorphic functions to broader complex-analytic settings, including holomorphic curves and several complex variables. Their work explains why exceptional values and ramification can be controlled by growth estimates [1].

3. Theory

Core theory

250. Counting, proximity, and characteristic.

Let $n(r, f)$ count poles of f in $|z| \leq r$, with multiplicity. The integrated counting function is

$$N(r, f) = \int_0^r \frac{n(t, f) - n(0, f)}{t} dt + n(0, f) \log r.$$

It records how pole counts accumulate with radius. For a value a , use $N(r, a, f) = N(r, 1/(f - a))$; for $a = \infty$, use $N(r, f)$.

The proximity function $m(r, a, f)$ measures how close f is to a on the circle $|z| = r$, averaged logarithmically. The characteristic

$$T(r, f) = N(r, a, f) + m(r, a, f) + O(1)$$

measures overall growth and is essentially independent of a . The Ahlfors–Shimizu version expresses the same growth through spherical area.

251. First fundamental theorem.

The first fundamental theorem says that for every a on the Riemann sphere,

$$T(r, f) = N(r, a, f) + m(r, a, f) + O(1).$$

Thus a function's growth is divided between actually taking a value and approaching it on the boundary. Algebraic identities give $T(r, fg) \leq T(r, f) + T(r, g) + O(1)$, $T(r, 1/f) = T(r, f) + O(1)$, and $T(r, f^m) = mT(r, f) + O(1)$.

252. Second fundamental theorem and defects.

The second fundamental theorem compares several distinct values. Roughly, a nonconstant meromorphic function cannot avoid too many values without paying a growth cost. For distinct $a_1, \dots, a_q$,

$$(q-2)T(r, f) \leq \sum_{j=1}^q \overline{N}(r, a_j, f) + S(r, f),$$

where multiplicities are truncated in $\overline{N}$ and S is small relative to T outside an exceptional set.

The defect $\delta(a, f)$ measures how often f fails to take a compared with the growth expected from the first theorem. The defect relation says the total defect is at most two for a nonconstant meromorphic function in the plane. A value may be omitted completely only in exceptional ways.

253. Picard and differential equations.

Using the second theorem with three values, one obtains Picard's theorem: a transcendental entire function takes every complex value, with at most one exception, infinitely often. A meromorphic function has at most two omitted values. The logarithmic derivative lemma controls $m(r, f'/f)$ and supports differential equations involving meromorphic functions.

Nevanlinna theory studies uniqueness questions: if two meromorphic functions take the same values with prescribed multiplicities, when must they be identical? It also treats algebroid functions, holomorphic curves, maps between complex manifolds, quasiregular maps, and minimal surfaces [2].

254. What the theory depends on and where it is useful.

Nevanlinna theory depends on complex analysis, Jensen's formula, harmonic functions, and asymptotic estimates. It helps Diophantine approximation by comparing value distribution with height growth, and helps geometry through holomorphic curves and minimal surfaces.

The estimates usually hold outside exceptional sets of radii and often give asymptotic rather than exact information. The definition of a small error term must be stated carefully.

4. Important theorems and results

- (a) **First fundamental theorem.** $T = N + m + O(1)$ for every target value.
- (b) **Second fundamental theorem.** A meromorphic function cannot strongly avoid too many distinct values without large growth.
- (c) **Defect relation.** The sum of defects of a meromorphic function is at most two.
- (d) **Picard theorem.** A transcendental entire function omits at most one complex value; a meromorphic function omits at most two values.
- (e) **Logarithmic derivative lemma.** The proximity of f'/f is small compared with $T(r, f)$ outside an exceptional set [3].

Nevanlinna's characteristic $T(r, f)$ measures the growth of a meromorphic function, while N counts its values and m measures how often values are missed. The first theorem balances these terms; the second limits how many values can be missed; and the defect relation summarizes that limit. Picard's theorem is the sharp qualitative consequence, while the logarithmic derivative lemma supplies a technical estimate used in proving the stronger results.

255. Applications.

- (a) **Value distribution in signal processing.** In signal analysis, the short-time Fourier transform of a signal is a holomorphic function of frequency and time. Nevanlinna's second fundamental theorem implies that this function cannot simultaneously avoid too many target values—interpreted as spectral levels—without paying a growth cost in the characteristic $T(r, f)$. This constraint manifests in practice as a lower bound on the number of time-frequency cells that a signal must occupy for a given bandwidth. Radar and sonar waveform design exploits this limitation: a waveform whose ambiguity function avoids too many amplitude levels must be spread across more time-frequency cells, reducing resolution. Engineers use the defect relation to quantify the unavoidable trade-off between range

resolution and Doppler resolution, linking the Nevanlinna defect $\delta(a, f)$ to the minimum number of resolvable bins in a spectrogram [1, 2].

- (b) **Approximation theory and rational interpolation.** The poles and zeros of rational approximants to a function f on a domain are meromorphic data, and Nevanlinna's counting function $N(r, f)$ measures their density. In Padé and rational Chebyshev approximation, the rate at which approximation error decreases is controlled by how the poles of the approximant distribute themselves. The defect relation provides a rigorous upper bound on how many exceptional target values (poles outside a prescribed region) can exist: if the rational approximant avoids too many prescribed pole locations, the characteristic growth forces the approximation error to remain large. This result is used in model-order reduction for linear dynamical systems, where engineers seek low-order transfer functions that match frequency-response data at prescribed frequencies while keeping the reduced model's poles in stable regions of the complex plane [2, 3].

6. Connections

Using existing theories

- (a) Complex analysis supplies meromorphic functions and zeros, measure theory supplies angular averages, and asymptotic analysis compares growth terms.
- (b) Diophantine approximation and value distribution provide the arithmetic and geometric interpretations.

Helping other theories

- (a) Nevanlinna theory helps complex analysis control how often a meromorphic function takes values and helps arithmetic geometry study rational and integral points.
- (b) Its counting and proximity functions turn qualitative value-avoidance questions into quantitative growth estimates.

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1.** What does $N(r, f)$ count?

Solution. It is an integrated count of poles of f inside the disk of radius r , including multiplicity and weighting poles according to their distance from the origin.

- (b) **Exercise 2.** What does $T(r, f)$ measure?

Solution. It measures total growth, combining how often a value is taken with how close the function comes to that value on the boundary.

- (c) **Exercise 3.** How many values can a transcendental entire function omit?

Solution. At most one. This is Picard's theorem; omitting two values is impossible for a nonconstant entire transcendental function.

- (d) **Exercise 4.** Why are multiplicities sometimes truncated?

Solution. Truncation emphasizes distinct target points rather than allowing one highly repeated solution to dominate the count.

- (e) **Exercise 5.** What is a defect?

Solution. It measures the fraction of expected value-distribution growth missing at a target value. A completely omitted value has maximal defect.

Chapter 57

Number theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How can we understand the exact patterns hidden in whole numbers, especially in prime numbers?

Formal

Number theory studies the integers, divisibility, remainders, primes, equations, and the ways numbers can be approximated or represented. It begins with familiar arithmetic but reaches algebra, geometry, probability, and computing. Its central method is to replace a large numerical question by a structural one: instead of testing every possibility, factor a number, work with its remainder, or study the shape of all solutions.

2. History

Historical development

- (a) The question and its history.

The objects of number theory are numbers such as $0, 1, 2, \dots$, the negative integers, fractions, and numbers obtained from polynomial equations. A typical question is whether an equation such as $x^2 + y^2 = z^2$ has solutions, or whether a very large integer is prime. These questions are exact: a numerical experiment can suggest a pattern, but a proof must explain why the pattern continues forever [1].

The subject has several connected parts. Elementary number theory studies divisibility, primes, congruences, Diophantine equations, continued fractions, and partitions. Analytic number theory uses limits and complex functions to study how primes are distributed. Algebraic number theory enlarges the integers to number systems in which polynomial equations become easier to understand. Geometric and arithmetic geometry study integer and rational solutions using curves and higher-dimensional shapes. Probabilistic, combinatorial, computational, and applied number theory use randomness, counting, algorithms, and applications [1, 2].

Babylonian tablets record calculations involving right triangles. Greek mathematicians made the theory deductive: Euclid proved that every integer has one prime factorization and that there are infinitely many primes. Diophantus studied equations in integers and rational numbers. The Chinese remainder theorem was developed in ancient China, while Indian mathematicians such as Aryabhata, Brahmagupta, and Bhaskara developed methods for indeterminate equations. In the seventeenth and eighteenth centuries Fermat, Euler, Lagrange, and Legendre created much of modern elementary number theory. Gauss organized congruences and quadratic forms, and nineteenth-century mathematicians connected numbers with algebra and complex analysis [1, 3].

3. Theory

Core theory

256. The basic tools.

If a and b are integers, we say that a divides b when $b = ak$ for another integer k . Division with remainder says that for $a > 0$

there are unique integers q and r with

$$b = aq + r, \quad 0 \leq r < a.$$

Repeated division gives the Euclidean algorithm for the greatest common divisor. For example,

$$252 = 2(105) + 42, \quad 105 = 2(42) + 21,$$

so $\gcd(252, 105) = 21$. Reversing these steps also writes the greatest common divisor as an integer combination of the original numbers. This is the extended Euclidean algorithm, and it produces modular inverses [1].

The fundamental theorem of arithmetic says that every integer greater than 1 can be written as a product of primes, and that the product is unique apart from the order of the factors. Thus $84 = 2^2 \cdot 3 \cdot 7$ in only one essential way. This theorem turns divisibility into bookkeeping with prime exponents. It also explains why the greatest common divisor takes the smaller exponent of each prime and the least common multiple takes the larger exponent [1].

Congruence notation records remainders. We write $a \equiv b \pmod{m}$ when m divides $a - b$. The statement $3x \equiv 1 \pmod{7}$ has solution $x \equiv 5 \pmod{7}$, because $3 \cdot 5 = 15 \equiv 1 \pmod{7}$. A number has a multiplicative inverse modulo m precisely when it is relatively prime to m . Congruences allow a difficult calculation to be reduced to a small finite table while preserving the information needed for divisibility [1].

257. Equations and patterns.

A Diophantine equation asks for integer or rational solutions. The equation $ax + by = c$ has an integer solution exactly when $\gcd(a, b)$ divides c . For example, $6x + 15y = 9$ is solvable because $\gcd(6, 15) = 3$ divides 9. The solutions form an infinite arithmetic family once one solution is known. Equations such as $x^2 + y^2 = z^2$, Pell's equation $x^2 - Dy^2 = 1$, and Fermat-type equations require more specialized ideas [1, 3].

Continued fractions approximate a real number by fractions while controlling the error. The expansion of $\sqrt{2}$ begins

$$\sqrt{2} = [1; 2, 2, 2, \dots],$$

whose convergents include 1, $3/2$, $7/5$, and $17/12$. These are unusually good approximations. Continued fractions therefore solve approximation problems and also provide a way to analyze quadratic irrational numbers and Pell equations [1].

Prime numbers are the indivisible building blocks of the integers. Their abundance is described asymptotically by the prime number theorem:

$$\pi(x) \sim \frac{x}{\log x},$$

where $\pi(x)$ counts primes at most x . The formula does not identify the next prime, but it predicts the density of primes for large x . Riemann's zeta function and Dirichlet L -functions give analytic tools for studying finer questions, including primes in arithmetic progressions. The Riemann hypothesis is a famous unproved conjecture about the zeros of the zeta function [2].

258. How the theory solves practical problems.

Modern cryptography uses number theory because multiplication of large primes is fast, while recovering the primes from their product can be difficult. In RSA, a public key contains a large composite number $n = pq$ and an exponent; a private key is built from the hidden factors p and q . Modular exponentiation encrypts and decrypts messages, while Euler's theorem explains why the operations undo one another for permitted messages [2].

The Chinese remainder theorem combines separate remainder conditions. If $x \equiv 2 \pmod{3}$ and $x \equiv 3 \pmod{5}$, then $x \equiv 8 \pmod{15}$. This is useful in computer arithmetic because a large calculation can be performed modulo several smaller, coprime numbers and then recombined. Error-correcting codes use finite fields and polynomial arithmetic to add redundancy, allowing a receiver to reconstruct data after some symbols are changed [2].

Elliptic curves provide another example. An equation such as $y^2 = x^3 + ax + b$ defines a curve with a special addition rule for its points. The arithmetic of these points supports digital signatures and key exchange. The security is not based on multiplication alone but on the difficulty of reversing a point-multiplication operation on a suitably chosen curve [3].

4. Important theorems and results

- (a) **Euclid's theorem on primes.** There are infinitely many primes. If $p_1, \dots, p_k$ were all the primes, the number $p_1 p_2 \cdots p_k + 1$ would have a prime factor not on the list.
- (b) **Fundamental theorem of arithmetic.** Every integer greater than 1 has one prime factorization.
- (c) **Bézout's identity.** There exist integers u, v such that $ua + vb = \gcd(a, b)$. This is the reason the extended Euclidean algorithm finds inverses.
- (d) **Chinese remainder theorem.** Compatible congruences with pairwise coprime moduli have one solution modulo the product of the moduli.
- (e) **Fermat's little theorem and Euler's theorem.** If p is prime and p does not divide a , then $a^{p-1} \equiv 1 \pmod{p}$. More generally, $a^{\varphi(n)} \equiv 1 \pmod{n}$ when $\gcd(a, n) = 1$.
- (f) **Prime number theorem.** The proportion of integers near x that are prime is approximately $1/\log x$. It describes average distribution, not an exact list.

Source for these results: [1].

5. Applications

Divisibility, congruences, primes, and Diophantine equations organize the arithmetic structure of integers and related rings.

- (a) Public-key cryptography
- (b) error-correcting codes
- (c) fast computer arithmetic
- (d) calendars
- (e) random-number generation
- (f) digital signatures
- (g) and the analysis of patterns in data.

6. Connections

Using existing theories

- (a) Integer arithmetic supplies divisibility and congruence, while algebra turns those rules into groups, rings, and fields that can be manipulated systematically.
- (b) Proof identifies which patterns are universal, and analysis becomes necessary when infinitely many integers are counted or primes are studied through generating functions.
- (c) For example, reducing modulo m turns an infinite search for solutions into a finite search among residue classes, while a zeta function packages information about all primes into one analytic object [1, 2].

Helping other theories

- (a) Number theory helps coding theory by providing finite-field arithmetic in which errors can be detected and corrected.
- (b) Cryptography uses modular exponentiation together with problems such as factoring or discrete logarithms that are easy to perform in one direction but difficult to reverse.
- (c) Algebraic geometry and probability borrow arithmetic counts and congruence information, while mathematical physics uses lattices, modular forms, and spectral sums to organize discrete states [1, 2].

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1. Compute $\gcd(252, 105)$ and express it as a combination.** The Euclidean algorithm gives $252 = 2(105) + 42$ and $105 = 2(42) + 21$. Hence the gcd is 21. Since $21 = 105 - 2(42) = 105 - 2(252 - 2(105)) = 5(105) - 2(252)$, one combination is $21 = -2(252) + 5(105)$.

- (b) **Exercise 2. Solve** $14x \equiv 8 \pmod{22}$. The gcd of 14 and 22 is 2, which divides 8. Divide by 2 to get $7x \equiv 4 \pmod{11}$. Since $7^{-1} \equiv 8 \pmod{11}$, $x \equiv 32 \equiv 10 \pmod{11}$. The solutions modulo 22 are $x \equiv 10, 21 \pmod{22}$.
- (c) **Exercise 3. Solve** $x \equiv 2 \pmod{3}$ **and** $x \equiv 3 \pmod{5}$. Write $x = 2 + 3k$. Then $2 + 3k \equiv 3 \pmod{5}$, so $3k \equiv 1 \pmod{5}$. The inverse of 3 modulo 5 is 2, giving $k \equiv 2 \pmod{5}$ and $x \equiv 8 \pmod{15}$.
- (d) **Exercise 4. Prove that** $\sqrt{2}$ **is irrational.** Suppose $\sqrt{2} = a/b$ in lowest terms. Then $a^2 = 2b^2$, so a is even, say $a = 2c$. Substitution gives $b^2 = 2c^2$, so b is even too, contradicting that a/b was reduced. Thus no fraction equals $\sqrt{2}$.
- (e) **Exercise 5. Find the positive integer solutions of** $3x + 5y = 1$. Since $3(2) + 5(-1) = 1$, one solution is $(2, -1)$. The general solution is $x = 2 + 5t$ and $y = -1 - 3t$ for integers t , because changing x by 5 and y by -3 preserves the left side.

Chapter 58

Obstruction theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How can we tell that a construction cannot be completed, even when every small piece looks possible?

Formal

Obstruction theory turns a failed extension into a class that can be calculated. If the class is nonzero, completion is impossible; if it vanishes, the extension is often possible, at least up to continuous deformation. The theory therefore converts a vague failure into a precise cohomological invariant.

2. History

Historical development

(a) The idea and its history.

Suppose a map has been defined on the edges of a triangulated shape. We would like to fill in each triangle, then each

tetrahedron, and so on. A boundary may carry a twist that prevents the next filling. Obstruction theory records that twist instead of trying all possible fillings. The modern language grew from the work of Stiefel and Whitney on characteristic classes and from Samuel Eilenberg's systematic obstruction theory for homotopy [1, 2].

The word obstruction is important: it is not merely evidence that a particular attempt failed. It is an invariant of the already-defined boundary data. Changing the construction without changing its homotopy class changes the representative but not the essential cohomology class. This is why a local calculation can give a global impossibility result [3].

3. Theory

Core theory

259. Extending a map skeleton by skeleton.

A simplicial complex is made from vertices, edges, triangles, tetrahedra, and higher-dimensional simplices. Its n -skeleton is the part made from pieces of dimension at most n . Let a continuous map from a complex X to a space Y already be defined on the $(n-1)$ -skeleton. To extend it across an n -simplex, we must extend its boundary map from an $(n-1)$ -sphere to the inside of the simplex.

The boundary map determines an element of the homotopy group $\pi_{n-1}(Y)$. If that element is nonzero, the boundary is wrapped around Y in a way that cannot be filled. Assigning this element to every n -simplex gives an n -cochain. Compatibility on adjacent faces makes it a cocycle, so it determines a class in

$$H^n(X; \pi_{n-1}(Y)).$$

The class is the obstruction to extending the map. A zero class means that the map can be adjusted within its homotopy class so that extension is possible; a nonzero class proves that extension is impossible [1].

260. Concrete illustration: computing an obstruction on a 2-skeleton.

Let X be a simplicial complex consisting of three vertices v_0, v_1, v_2 , three edges e_{01}, e_{02}, e_{12} , and one triangle Δ with boundary $e_{01} + e_{12} - e_{02}$. Let $Y = S^1$ (the unit circle). We want to extend a map $f: X^{(1)} \rightarrow S^1$ from the 1-skeleton to the whole complex.

Step 1: Define f on vertices. Set $f(v_0) = f(v_1) = f(v_2) = 1 \in S^1$.

Step 2: Define f on edges. Let f traverse the circle once around each edge: each edge maps by the identity loop $e^{2\pi it}$ for $t \in [0, 1]$. The winding number on every edge is 1.

Step 3: Compute the obstruction on Δ . The boundary of Δ maps into S^1 with total winding $1 + 1 - 1 = 1$. This nonzero element of $\pi_1(S^1) \cong \mathbb{Z}$ is the obstruction cocycle on Δ . Its cohomology class in $H^2(X; \pi_1(S^1))$ is $1 \neq 0$.

Conclusion. No continuous extension of f to the interior of Δ exists. The obstruction computation took three concrete steps—assign values, sum winding numbers, check nonzero—that generalize to any dimension by replacing winding numbers with higher homotopy groups [3].

For a simple picture, a map from the circle to the circle may wind around once. The winding number is nonzero, so it cannot extend to a map from the disk to the circle without crossing the circle's missing center in an appropriate model. A map that winds zero times can be filled. The same reasoning survives in much more complicated spaces, where the winding number is replaced by a homotopy group and cohomology class.

261. Sections and bundles.

A bundle is a space that locally looks like a product: above each point of a base B sits a fiber F . A section chooses one point in every fiber continuously. A section of a vector bundle is a continuous vector field; a nowhere-zero section is a vector field that never vanishes. The question is global because local choices may disagree when they are moved around loops.

Let $p: E \rightarrow B$ be a fibration with fiber F , and suppose a section has been built on the n -skeleton of B . On the boundary of each $(n + 1)$ -simplex, the section gives a map from an n -sphere into the fiber. Its homotopy class lies in $\pi_n(F)$. These classes form an

obstruction cochain in

$$C^{n+1}(B; \pi_n(F)).$$

It is a cocycle, and its cohomology class in $H^{n+1}(B; \pi_n(F))$ is independent of the earlier choices up to a coboundary. If it is nonzero, no extension exists. Under the usual hypotheses, if it is zero, a homotopy section exists on the next skeleton [2].

Characteristic classes are important examples. The Stiefel–Whitney classes and Euler class can obstruct independent vector fields or nowhere-zero sections. The famous hairy-ball phenomenon says that a continuous tangent vector field on an even-dimensional sphere must vanish somewhere; in obstruction language, a characteristic class prevents a nowhere-zero section [3].

262. Geometry and surgery.

In geometric topology, obstruction theory asks whether a topological manifold admits a piecewise-linear structure, and whether a piecewise-linear manifold admits a differentiable structure. In dimensions at most two, and in dimension three by Moise’s theorem, the relevant topological and piecewise-linear notions agree. Dimension four is exceptional: topological and smooth questions diverge sharply. In dimensions at most six, piecewise-linear and differentiable structures coincide in the standard comparison described in the subject [4].

Surgery theory asks whether a space satisfying n -dimensional Poincaré duality is homotopy equivalent to a manifold, and whether a homotopy equivalence between manifolds can be changed into a diffeomorphism. In high dimensions there is first a primary topological K -theory obstruction to obtaining a suitable vector bundle and normal map. If it vanishes, a secondary obstruction in algebraic L -theory decides whether surgery can produce the desired homotopy equivalence [4, 5].

263. How it is useful.

The method is useful whenever a problem is staged by dimension. In topology it tells us the first dimension in which a map, field, or structure fails. In bundle theory it separates local triviality from global triviality. In manifold theory it organizes a difficult classification into a sequence of computable tests. In motion planning, the

same idea appears when a locally chosen motion cannot be patched into one continuous rule over all configurations.

4. Important theorems and results

- (a) **Eilenberg obstruction theorem.** The obstruction to extending a map across the n -skeleton is a class in $H^n(X; \pi_{n-1}(Y))$.
- (b) **Extension criterion.** A zero obstruction class permits extension after changing the map within its homotopy class; a nonzero class forbids extension.
- (c) **Bundle-section obstruction.** For a fibration with fiber F , extending a section across the $(n+1)$ -skeleton produces a class in $H^{n+1}(B; \pi_n(F))$.
- (d) **Characteristic-class principle.** Characteristic classes measure the failure of a bundle to possess specified global fields or sections.
- (e) **Moise's theorem.** Every topological 3-manifold has a unique piecewise-linear and smooth structure up to the appropriate equivalence.
- (f) **Surgery obstruction principle.** In high-dimensional manifold problems, a primary K -theory obstruction is followed, when it vanishes, by a secondary algebraic L -theory obstruction.

Source for these results: [1].

5. Applications

Cohomology classes and obstruction groups identify the first stage at which a local construction cannot extend globally.

- (a) Extending maps
- (b) constructing sections of bundles
- (c) deciding whether bundles are trivial
- (d) classifying manifolds
- (e) and the existence questions of surgery theory.

6. Connections

Using existing theories

- (a) Topology supplies the space and homotopy theory supplies the idea that a construction should be unchanged by continuous deformation.
- (b) A partial construction is extended one cell at a time; when an extension fails on the boundary of the next cell, the failure is recorded as a cohomology class with values in a homotopy group.
- (c) If that class vanishes, the construction can continue, so cohomology turns an existence question into a sequence of computable tests [1, 2].

Helping other theories

- (a) The method helps bundle theory decide whether a section or reduction of structure group exists, and helps Postnikov theory build a space from successive homotopy data.
- (b) In surgery and K- or L-theory, the same pattern tests whether algebraic data can be realized by an actual manifold or bundle.
- (c) The obstruction is therefore useful precisely because it identifies the first stage at which a proposed construction cannot be completed [3, 4].
- (d) **Structural engineering and failure modes.** A loaded truss or frame is a network of beams (edges) joined at nodes (vertices). Each beam can carry stress in certain directions—the “fiber” of the local bundle. When an engineer tries to assign a consistent stress distribution across the whole structure, local solutions may fail to patch together globally. The obstruction cocycle measures exactly this: a nonzero class in $H^2(B; \pi_1(F))$ signals a load path that cannot close, predicting a failure mode such as torsional buckling or a mechanism (a floppy mode). For instance, a cantilevered roof frame with triangular bracing has trivial obstruction classes, confirming rigidity; removing one diagonal makes a class nonzero, identifying the precise panel where collapse initiates [2].

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1. Why can a degree-one map from a circle to a circle not extend over a disk?** The boundary map has winding number one. Winding number is its class in $\pi_1(S^1) \cong \mathbb{Z}$, and it is nonzero. Therefore it is the obstruction to filling the circle by a disk map.
- (b) **Exercise 2. What is the obstruction group for extending a map from the boundary of a 4-simplex into Y ?** The boundary of a 4-simplex is a 3-sphere. Its class lies in $\pi_3(Y)$. For a complex, the corresponding cochain has degree four and usually contributes to $H^4(X; \pi_3(Y))$.
- (c) **Exercise 3. A section over the 1-skeleton has obstruction classes $c_\Delta = 0$ for every 2-simplex. What follows?** The obstruction cochain is zero, so the section extends over the 2-skeleton. This conclusion concerns existence at that stage; later skeletons may have new obstructions.
- (d) **Exercise 4. Why does changing a partial section alter the obstruction cochain by a coboundary?** The two sections agree on the previous skeleton. Their difference is therefore represented by a cochain on the current cells, and the boundary of that cochain measures the change on the next cells. Hence the obstruction classes represent the same cohomology element.
- (e) **Exercise 5. What is the first test in the high-dimensional surgery pattern?** One first checks the primary topological K -theory obstruction to producing a vector bundle and normal map. Only if it vanishes is it meaningful to calculate the secondary obstruction in algebraic L -theory.

Chapter 59

Operator theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How can we study transformations of functions, signals, and infinite lists as carefully as we study numbers?

Formal

An operator is a rule that takes one object to another, often a function to a function. Operator theory studies linear and nonlinear operators, their domains, inverses, spectra, and natural modes. It extends matrix algebra to infinite-dimensional spaces, where convergence and the choice of domain become part of the problem.

2. History

Historical development

(a) **The problem and its history.**

Matrices act on finite lists of numbers. Differentiation, integration, shifting a sequence, and filtering a signal act on functions

or infinite lists. These rules are too large to be represented by a finite matrix, but they still have structure. Operator theory asks which rules are continuous, which can be inverted, how errors grow, and whether the rule has simple modes [1].

The subject began with differential and integral operators arising in differential equations. Hilbert's study of integral equations introduced infinite-dimensional analogues of Euclidean space. Banach and von Neumann developed the language of normed and Hilbert spaces, while spectral theory connected operators to eigenvalues. The resulting theory belongs to functional analysis and depends heavily on the topology of function spaces [2, 3].

3. Theory

Core theory

264. Operators and their domains.

Let X and Y be vector spaces. A linear operator $T : X \rightarrow Y$ satisfies

$$T(ax + by) = aT(x) + bT(y).$$

The differentiation operator D sends a polynomial x^n to nx^{n-1} . Its kernel consists of constant polynomials, and its range on polynomials is all polynomials. An integral operator may have the form

$$(Tf)(x) = \int_a^b K(x, t)f(t) dt,$$

where the kernel K describes how input values are combined.

In finite dimensions every linear map is defined on the whole space and is continuous. For an unbounded operator such as differentiation on a space of square-integrable functions, the domain must be specified. A function may be square-integrable while its derivative is not. Ignoring this point can make a formally correct equation meaningless. Closed operators and densely defined operators provide the setting in which limits and adjoints can be handled safely [1, 2].

265. Spectrum and natural modes.

For a matrix A , an eigenvector v satisfies $Av = \lambda v$. The corresponding λ is a value at which $A - \lambda I$ fails to be invertible. In an infinite-dimensional space, the spectrum of T is the set of complex numbers λ for which $T - \lambda I$ has no bounded inverse. The spectrum may contain values that are not ordinary eigenvalues; this is one reason infinite-dimensional analysis is richer than matrix algebra.

The spectral theorem says, broadly, that self-adjoint and more generally normal operators can be represented using their spectral data. In finite dimensions a normal matrix is unitarily diagonalizable:

$$A = UDU^*,$$

where the columns of U are orthonormal eigenvectors and D is diagonal. For an infinite-dimensional self-adjoint operator, a sum over eigenvectors may be replaced by an integral over a spectral measure. The operator then behaves like multiplication by the variable, the simplest possible model [1, 4].

An operator N on a complex Hilbert space is normal when $NN^* = N^*N$. Unitary operators preserve lengths, self-adjoint operators are the infinite-dimensional analogue of Hermitian matrices, and positive operators have the form M^*M . These classes are important because the spectral theorem applies to them and because they model reversible motion, measured quantities, and energy [1].

266. Polar decomposition.

Every bounded operator A between complex Hilbert spaces has a canonical factorization

$$A = UP, \quad P = (A^*A)^{1/2},$$

where P is positive and U is a partial isometry. For a square invertible matrix, this says that A is a rotation or reflection followed by a stretch. It is the operator version of writing a complex number as magnitude times direction, and it is closely related to the singular value decomposition.

The word partial matters in infinite dimensions. The unilateral shift on sequences moves every entry one place and inserts a zero. It preserves length on its initial space but is not onto, so it is not unitary. The polar factor records exactly this loss of surjectivity [3].

267. Complex analysis and operator algebras.

Many operators act on spaces of holomorphic functions. On the Hardy space, multiplication by the independent variable gives the unilateral shift. Beurling's theorem describes its invariant subspaces by inner functions. Toeplitz operators multiply a function and then project it back into the Hardy space; similar questions arise on Bergman spaces [5].

An operator algebra is a collection of operators closed under addition, scalar multiplication, and composition. A C^* -algebra is a complex Banach algebra equipped with an adjoint operation satisfying

$$(xy)^* = y^*x^*, \quad (x^*)^* = x, \quad \|x^*x\| = \|x\|^2.$$

The norm identity is powerful: it ties algebraic invertibility, geometry, and spectral radius together. Commutative C^* -algebras can be understood through spaces of functions, while noncommutative ones provide an algebraic language for quantum observables [4].

268. How the theory solves applications.

For a vibrating string, separation of variables turns the wave equation into an eigenvalue problem for a differential operator. The eigenfunctions are normal modes; the observed motion is a combination of them. For a quantum particle, a self-adjoint operator represents an observable, and its spectrum describes the possible measurement values. The spectral theorem explains how probabilities are assigned to spectral regions [1].

In signal processing, a filter is an operator. Fourier modes are especially useful because convolution operators act on them by multiplication. Instead of tracking every point of a signal, one studies how the operator changes each frequency. In control theory, the spectrum of a system operator helps determine stability; in inverse problems, compact operators explain why recovering an input from measured output may amplify noise [2, 3].

4. Important theorems and results

- (a) **Spectral theorem.** Self-adjoint and normal operators on Hilbert spaces admit a spectral representation; finite-dimensional versions are unitary diagonalization.

- (b) **Schur decomposition.** Every complex matrix is unitarily similar to an upper triangular matrix. A normal upper triangular matrix is diagonal, yielding the normal-matrix spectral theorem.
- (c) **Polar decomposition.** Every bounded operator has $A = U(A^*A)^{1/2}$ with U a partial isometry, uniquely determined on the relevant range.
- (d) **Douglas factorization lemma.** If $A^*A \leq B^*B$, then $A = CB$ for a contraction C . This gives a clean route to polar decomposition.
- (e) **Beurling's theorem.** The invariant subspaces of the unilateral shift on the Hardy space are generated by inner functions.
- (f) **C^* -identity and spectral radius.** In a C^* -algebra the norm is determined by the algebraic structure through the spectrum of x^*x . This is why C^* -algebras are rigid analytic objects.

Source for these results: [1].

5. Applications

Domains, spectra, resolvents, and functional calculus extend matrix methods to transformations of infinite-dimensional spaces.

- (a) Differential and integral equations
- (b) quantum mechanics
- (c) Fourier analysis
- (d) signal processing
- (e) control
- (f) inverse problems
- (g) and the mathematics of operator algebras.

6. Connections

Using existing theories

- (a) Linear algebra studies transformations of finite-dimensional vectors; operator theory extends the same question to spaces of functions, where convergence and integration must be controlled.
- (b) Topology of function spaces says which limits are allowed, measure defines the integral norms, and complex analysis explains resolvents and spectra.
- (c) For example, differentiating a function is an operator, and asking for its eigenfunctions is asking which shapes reproduce themselves under differentiation or under a boundary-value problem [1, 2].

Helping other theories

- (a) Operator theory helps differential equations by converting an equation into a statement about an operator's inverse or spectrum.
- (b) Fourier analysis diagonalizes important translation-invariant operators into frequencies, while quantum mechanics interprets observables as operators and their spectra as possible measurement values.
- (c) In control and inverse problems, boundedness and spectral location tell whether errors grow and whether hidden inputs can be recovered [1, 4].

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1. Find the eigenvalues and an orthonormal eigenbasis of $A = \begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix}$.** The vectors $(1, 1)$ and $(1, -1)$

- give eigenvalues 3 and 1. After dividing each by $\sqrt{2}$, they form an orthonormal basis, so A is unitarily diagonalizable.
- (b) **Exercise 2. What is the kernel of differentiation on polynomials?** If $Dp = 0$, every coefficient of positive degree is zero, so p is constant. Thus $\ker D$ is the one-dimensional space of constants.
- (c) **Exercise 3. Compute the polar decomposition of**
 $A = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}$. We have $A^*A = \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix}$, so $P = (A^*A)^{1/2} = \text{diag}(0, 1)$. The partial isometry U sends $(0, 1)$ to $(1, 0)$ and is zero on $(1, 0)$; then $UP = A$.
- (d) **Exercise 4. Why is the differentiation operator unbounded on $L^2[0, 1]$?** Take $f_n(x) = \sin(2\pi nx)$. Its L^2 norm stays fixed while the derivative has norm proportional to n . No single constant bounds $\|Df\|$ by $\|f\|$, so differentiation is not bounded on this space.
- (e) **Exercise 5. Explain the Fourier reason that convolution becomes multiplication.** A Fourier mode $e^{i\omega x}$ is an eigenfunction of translation. Convolution with a fixed kernel preserves each frequency and multiplies its amplitude by the kernel's Fourier transform. Therefore filtering can be performed frequency by frequency.

Chapter 60

Order theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How can we describe precedence, containment, or preference when some pairs can be compared and others cannot?

Formal

Order theory formalizes statements such as less than, comes before, is contained in, or is more specialized than. It studies partially ordered sets, bounds, lattices, order-preserving maps, chains, antichains, and the duality obtained by reversing an order.

2. History

Historical development

(a) The question and its history.

The everyday order on numbers compares every pair: either $2 < 3$, $3 < 2$, or they are equal. But the subset relation is different. The set of birds and the set of dogs are both subsets

of animals, but neither contains the other. Order theory was created to study both situations with one language [1].

George Boole, Charles Sanders Peirce, Richard Dedekind, and Ernst Schröder developed early algebraic descriptions of order. Pasch, Peano, Hilbert, and Veblen developed axioms for order in geometry. Bertrand Russell examined order and series in the foundations of mathematics. The modern subject grew because the same patterns appeared in algebra, logic, analysis, geometry, and computer science [1, 2].

3. Theory

Core theory

269. Relations and ordered sets.

A binary relation $\leq$ on a set P is a partial order when it is reflexive ($a \leq a$), antisymmetric (if $a \leq b$ and $b \leq a$, then $a = b$), and transitive (if $a \leq b$ and $b \leq c$, then $a \leq c$). A set with such a relation is a partially ordered set, or poset. A total order additionally requires every pair to be comparable.

The divisibility relation on positive integers is a poset: $a \leq b$ means a divides b . The numbers 2 and 3 are incomparable, while both divide 6. A Hasse diagram draws only the immediate comparisons, so it reveals the structure without clutter from transitivity. The subset relation on a power set gives another important example [1].

An element can be maximal without being greatest. In the set $\{2, 3\}$ under divisibility, both elements are maximal, but neither is greatest. This distinction matters in optimization: a solution can be impossible to improve in its own direction while another incomparable solution is also optimal in a different direction.

270. Bounds, lattices, and duality.

An upper bound of $S \subseteq P$ is an element above every member of S . The least upper bound, or supremum, is written $\sup S$ or $\bigvee S$. A lower bound and greatest lower bound are written $\inf S$ or $\bigwedge S$. For subsets ordered by inclusion, union is the least upper bound and intersection is the greatest lower bound. For positive integers

ordered by divisibility, the least common multiple is the join and the greatest common divisor is the meet [1].

Reversing every comparison produces the dual order. Every definition has a dual: upper becomes lower, least becomes greatest, join becomes meet, and chain becomes chain in the reversed picture. A theorem in one order immediately gives a dual theorem. This is a powerful economy of thought because the same proof often works after turning the Hasse diagram upside down [2].

A lattice is a poset in which every pair has a meet and a join. A complete lattice has these bounds for every subset. A directed-complete partial order guarantees suprema of directed subsets and is central in domain theory, where a program is approximated by increasingly informative partial computations. Distributive lattices satisfy

$$x \wedge (y \vee z) = (x \wedge y) \vee (x \wedge z).$$

Boolean algebras add complementation and model logical operations and digital circuits; Heyting algebras model constructive logic [3].

271. Functions between orders.

A function $f : P \rightarrow Q$ is monotone when $a \leq b$ implies $f(a) \leq f(b)$. It is order-reflecting when the reverse implication holds, and antitone when it reverses the order. An order embedding preserves and reflects comparisons. An order isomorphism is a bijective order-preserving map whose inverse is also order-preserving.

The successor function on natural numbers is monotone. The complement map on a power set is antitone: if $A \subseteq B$, then $B^c \subseteq A^c$. A closure operator is monotone, extensive ($x \leq f(x)$), and idempotent ($f(f(x)) = f(x)$). Examples include taking the span of a set of vectors, the topological closure of a set, and the set of all logical consequences of assumptions [3].

A Galois connection is a pair of monotone maps between two ordered sets that are almost inverse in a precise inequality sense. Such pairs explain why taking a set of objects and taking the properties common to those objects are closely related operations. They occur in formal concept analysis, algebra, and the correspondence between subgroups and fixed fields [4].

272. Special subsets and constructions.

An upper set contains every element above each of its members; a lower set contains everything below. An ideal is a directed lower set, and a filter is its dual. A chain is a subset in which every two elements are comparable. An antichain has no two comparable elements. These concepts are essential in combinatorics, especially when a large poset is decomposed into chains or antichains [1].

New orders can be built from old ones. The product order on $P \times Q$ is defined by $(p, q) \leq (p', q')$ exactly when $p \leq p'$ and $q \leq q'$. A disjoint union keeps the original comparisons but adds no comparisons between the two pieces. A strict order is obtained by writing $a < b$ when $a \leq b$ and $a \neq b$.

273. How the theory solves practical problems.

In project scheduling, a task is below another task when it must be completed first. A topological sort lists tasks in an order compatible with all dependencies. If two tasks are incomparable, they can be done in parallel. The existence of minimal available tasks is an order-theoretic fact, while the resulting algorithm is used in build systems and course planning.

In type systems, a type may be below another when every value of the first can safely be used where the second is expected. Monotone functions preserve safe substitutions. In databases, sets of records ordered by inclusion form lattices; union combines information and intersection keeps common information. In optimization with several objectives, the Pareto-optimal points form the maximal elements of a partial order, so order theory explains why there need not be one best choice [3].

4. Important theorems and results

- (a) **Zorn's lemma.** If every chain in a nonempty poset has an upper bound, the poset has a maximal element. It is equivalent to the axiom of choice and is used to prove the existence of bases and maximal ideals.
- (b) **Knaster–Tarski fixed-point theorem.** Every monotone map from a complete lattice to itself has a least fixed point and a greatest fixed point.

- (c) **Dilworth's theorem.** In a finite poset, the largest antichain has the same size as the smallest number of chains needed to cover the poset.
- (d) **Birkhoff representation theorem.** Every finite distributive lattice is isomorphic to the lattice of lower sets of a finite poset.
- (e) **Tarski's fixed-point principle.** Monotonicity on a complete lattice guarantees fixed points, turning repeated approximation into a rigorous existence method.
- (f) **Galois correspondence.** In suitable algebraic situations, inclusion-reversing correspondences between subobjects and substructures are organized by a Galois connection.

Source for these results: [1].

5. Applications

Partial orders, chains, antichains, and lattice operations describe how objects can be compared and combined without numerical coordinates.

- (a) Scheduling
- (b) dependency graphs
- (c) databases
- (d) optimization
- (e) type systems
- (f) logic
- (g) lattice-based algorithms
- (h) and the organization of mathematical structures.

6. Connections

Using existing theories

- (a) Sets provide the collection of objects and relations say when one object precedes, contains, or is more informative than another.

- (b) Transitivity and antisymmetry make comparisons consistent without requiring every pair to be comparable.
- (c) When two objects have a least common upper bound or greatest common lower bound, lattice operations combine information; logic and proof use these operations to track implication and approximation [1, 2].

Helping other theories

- (a) Order theory helps optimization because feasible solutions can be compared and a monotone improvement process can be shown to have a least or greatest fixed point.
- (b) In databases, an order can mean “contains at least this information,” so joins combine records without losing consistency.
- (c) In computer science and type theory, recursive definitions are interpreted as fixed points of ordered maps, while combinatorics uses chains and antichains to bound how a finite family can be arranged [1, 3].

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1. Find the meet and join of 12 and 18 in the divisibility order.** The meet is the greatest common divisor, $\gcd(12, 18) = 6$. The join is the least common multiple, $\text{lcm}(12, 18) = 36$.
- (b) **Exercise 2. Give two maximal elements that have no greatest element.** In the poset $\{2, 3\}$ ordered by divisibility, 2 and 3 are both maximal because neither has a larger member in the set divisible by it. There is no greatest element because neither divides the other.
- (c) **Exercise 3. Prove that the complement map on a power set is antitone.** If $A \subseteq B$, every element not in B

is also not in A . Therefore $B^c \subseteq A^c$, which is exactly order reversal.

- (d) **Exercise 4. Find the closure of $\{1, 2\}$ under taking divisors in the positive integers.** A divisor-closure contains every positive divisor of every selected number. The divisors of 1 and 2 are 1 and 2, so the closure is $\{1, 2\}$.
- (e) **Exercise 5. Use monotonicity to find a fixed point.** On the lattice $\mathcal{P}(\{a, b\})$, define $f(S) = S \cup \{a\}$. Starting at the bottom gives $\emptyset, \{a\}, \{a\}, \dots$. Thus the least fixed point is $\{a\}$. The other fixed point is also $\{a\}$, because every set containing a is sent to itself only when it contains no additional change; here $f(\{a, b\}) = \{a, b\}$ as well, so the greatest fixed point is $\{a, b\}$.

Chapter 61

Percolation theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. When a network is partly blocked or partly damaged, when does a large connected route suddenly appear or disappear?

Formal

Percolation theory studies random connectivity. Sites or links are declared open with a probability, and the theory asks whether open paths form a cluster spanning a region or continuing forever. A critical probability separates a disconnected phase from a connected phase.

2. History

Historical development

(a) The physical question and history.

Imagine pouring liquid onto porous rock. Each microscopic passage may be open or blocked. If open passages form a

connected route, liquid can travel from the top to the bottom. Percolation theory replaces the complicated material by a lattice or graph and studies the probability that a path exists. The model was introduced by Simon Broadbent and John Hammersley in 1957, after questions about gases and liquids moving through coal and other porous materials [1, 2].

3. Theory

Core theory

274. Sites, bonds, and the critical point.

In bond percolation, each edge of a graph is open with probability p and closed with probability $1 - p$, independently. In site percolation, each vertex is occupied with probability p , and an edge can be used only when its endpoints are occupied. The open cluster of a vertex is the set of vertices reachable by open paths.

$$p_c = \frac{1}{2}.$$

275. Phases and observables.

Below the threshold, open clusters are typically finite and connection probabilities decay rapidly. Above the threshold, a giant or infinite cluster appears while finite clusters remain around it. In two dimensions, duality relates open paths to closed paths in the dual lattice and compares the two phases [1].

Important observables include the probability that a site belongs to the infinite cluster, the mean cluster size, the correlation length, and the probability of a spanning path across a finite box. Near criticality these quantities often follow power laws such as $\xi \sim |p - p_c|^{-\nu}$. The exponent depends mainly on dimension rather than microscopic details, an idea called universality. Critical clusters are often fractal [2].

276. Critical exponents and universality.

Near the threshold, several quantities follow power laws whose exponents are called critical exponents. For example, the probability $\theta(p)$ that a site belongs to the infinite cluster behaves as $\theta(p) \sim (p -$

$p_c)^\beta$ for p slightly above p_c , the mean cluster size diverges as $\chi(p) \sim |p - p_c|^{-\gamma}$, and the correlation length scales as $\xi(p) \sim |p - p_c|^{-\nu}$. A central prediction of universality is that these exponents depend only on the lattice dimension and on the symmetry class of the model, not on microscopic details such as the lattice geometry or whether the model is site or bond percolation. Numerical simulations confirm this prediction: two-dimensional percolation yields a specific set of exponents, while three-dimensional percolation yields a different set, regardless of the underlying lattice [2].

277. Different models.

Directed percolation allows paths to move in a preferred direction such as time and is connected with the contact process. Bootstrap percolation activates or removes sites according to the number of active neighbors. First-passage percolation assigns random travel times to edges and studies the fastest route. Invasion percolation grows a cluster by choosing the least costly boundary edge. The Fortuin–Kasteleyn random-cluster model connects percolation with the Ising and Potts models [3].

278. How it solves real problems.

In epidemiology, people or animals are vertices and possible transmissions are edges. Below the transmission threshold, outbreaks usually die out in small clusters; above it, a large outbreak becomes possible. Vaccination or reduced contact can lower the effective connectivity and move a population below the threshold.

In ecology, habitat patches are sites and movement corridors are bonds. A species can persist over a region only if enough patches remain connected. In materials science, enough chemical links connect small polymer molecules into a system-spanning gel. In virology, randomly removing capsid subunits can cross a fragmentation threshold and break a virus shell [4].

279. Application: oil recovery and wireless connectivity.

In oil recovery, the pore space of a reservoir rock is modeled as a network in which open passages allow oil to flow. If the occupied pore fraction is below p_c , the oil remains trapped in disconnected pockets and cannot be extracted efficiently. Injecting surfactants or increasing the pressure effectively raises p_c 's complement, connecting enough pores for the oil to reach the production well. The

percolation threshold determines the minimum fraction of open pores needed for a spanning flow path, giving engineers a quantitative target for recovery design [4].

In wireless communication, each base station is a site and a communication link exists when two stations are close enough and the signal-to-noise ratio exceeds a threshold. The percolation threshold then predicts the density of base stations at which a giant connected component forms, enabling long-range communication across the network. Below the threshold, a mobile user can reach only a small local cluster; above it, end-to-end paths exist with high probability. This connection between spatial density and connectivity guides the deployment of ad hoc and sensor networks [1, 4].

4. Important theorems and results

- (a) **Existence of a critical threshold.** Standard infinite lattices have a value p_c separating the phase with no infinite open cluster from the phase with one.
- (b) **Kolmogorov zero–one law.** Translation-invariant tail events such as the existence of an infinite cluster have probability zero or one.
- (c) **Kesten’s square-lattice result.** Bond percolation on the planar square lattice has critical probability $p_c = 1/2$.
- (d) **Duality principle.** In two dimensions, open crossings and closed crossings in the dual lattice constrain one another.
- (e) **Sharpness of the transition.** In standard models, connection probabilities decay exponentially below the threshold, while a macroscopic cluster appears above it.
- (f) **Conformal invariance (Smirnov, 2001).** For critical bond percolation on the planar triangular lattice, the crossing probabilities of a simply connected domain converge to explicit conformally invariant functions as the lattice spacing tends to zero. This result proved the long-standing conjecture that two-dimensional critical percolation is conformally invariant in the scaling limit and is a key input in the derivation of exact critical exponents for two-dimensional percolation [1, 2].

Source for these results: [1].

5. Applications

Random open clusters and connectivity thresholds turn local occupation probabilities into global phase transitions.

- (a) Porous materials
- (b) epidemics
- (c) ecological habitats
- (d) power and transport networks
- (e) random graphs
- (f) polymer gelation
- (g) and the fragmentation of virus shells.

6. Connections

Using existing theories

- (a) Probability assigns independent or correlated open/closed states to edges or sites, while graph theory defines paths and connected components.
- (b) The central question is whether local random links create a global crossing or infinite cluster.
- (c) Statistical physics explains why a sharp threshold can appear: near a critical density, clusters occur on many scales, so a small change in the probability can change the large-scale behavior [1, 2].

Helping other theories

- (a) Percolation gives network reliability a concrete calculation: a communication network works when its open edges contain a path between two terminals.
- (b) The same cluster threshold models whether a disease can spread through a contact graph, whether fluid can pass through a porous material, or whether a random graph contains a giant component.

- (c) The theory supplies the bridge from local failure probabilities to a global connectivity prediction [1, 3].

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1. What is the expected number of open edges among 100 independent edges when $p = 0.3$?** Linearity of expectation gives $100(0.3) = 30$.
- (b) **Exercise 2. Why does a square-lattice bond model with $p = 0.4$ lie below its threshold?** Its threshold is $1/2$, and $0.4 < 1/2$, so an infinite open cluster does not occur in the infinite-lattice limit.
- (c) **Exercise 3. For a regular tree of degree 4, what is the threshold?** The formula $p_c = 1/(z - 1)$ gives $p_c = 1/3$.
- (d) **Exercise 4. Explain why site and bond percolation are different.** Bond percolation removes connections while keeping vertices. Site percolation removes vertices and all their incident connections, so the same probability can give different connectivity.
- (e) **Exercise 5. Why can reducing contacts reduce a large outbreak?** Removing contacts removes bonds and lowers connectivity. If the network crosses below its threshold, large outbreaks become unlikely even though small outbreaks remain possible.

Chapter 62

Perturbation theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How can we obtain useful answers when exact equations are too difficult, but are close to equations we can solve?

Formal

Perturbation theory separates a solvable problem from a small correction. The unknown solution is expanded in powers of a small parameter, and the equations for successive corrections are solved one at a time.

2. History

Historical development

(a) The idea and history.

The two-body gravitational problem has exact conic-section orbits, but the motion of three bodies does not generally have a simple closed formula. Astronomers treated the influence

of the third body as a perturbation of the two-body solution. Lagrange and Laplace developed systematic methods, and Le Verrier used deviations in Uranus's motion to predict Neptune [1, 2].

The same strategy entered quantum mechanics. Dirac developed time-dependent perturbation ideas, and physicists used corrections to calculate atomic energy shifts. Quantum field theory organizes repeated perturbative terms with Feynman diagrams [3].

3. Theory

Core theory

280. Regular perturbation.

Suppose a problem depends on a small number ε :

$$F(u, \varepsilon) = 0.$$

We seek

$$u = u_0 + \varepsilon u_1 + \varepsilon^2 u_2 + \cdots.$$

The zeroth-order equation gives u_0 . Substitution and comparison of powers of ε gives an equation for u_1 , then one for u_2 . Truncating after the first correction gives $u \approx u_0 + \varepsilon u_1$.

For $x^2 + \varepsilon x - 1 = 0$, put $x = x_0 + \varepsilon x_1 + \cdots$. At order zero choose $x_0 = 1$. At first order, $2x_0 x_1 + x_0 = 0$, giving $x_1 = -1/2$. Thus the positive root is $x \approx 1 - \varepsilon/2$ for small ε [1].

281. Orders and singular problems.

First-order perturbation keeps one correction, second-order keeps two, and so on. Higher order is not automatically better: the series may diverge, or a small parameter may multiply the highest derivative and create a boundary layer. Such a problem is singular because setting the parameter to zero changes the order of the equation.

Degeneracy occurs when the unperturbed problem has several independent states with the same value. The perturbation can mix those states, so one must first diagonalize the perturbing part within

the degenerate subspace. Multiple scales, matched asymptotic expansions, and dominant balance handle singular situations [2].

282. A mechanical example.

For a weakly nonlinear oscillator,

$$x'' + x + \varepsilon x^3 = 0,$$

the unperturbed motion is $x_0 = A \cos t$. A direct correction can contain a term proportional to $t \sin t$, which grows even though ε is small. This secular term signals that the frequency has shifted. The method of multiple scales introduces a slow time $T = \varepsilon t$ and allows the phase to vary slowly, removing the artificial growth.

283. Quantum and celestial applications.

In time-independent quantum mechanics,

$$H = H_0 + \varepsilon V.$$

If $H_0 \psi_n^{(0)} = E_n^{(0)} \psi_n^{(0)}$, then for a nondegenerate level the first energy correction is

$$E_n^{(1)} = \langle \psi_n^{(0)}, V \psi_n^{(0)} \rangle.$$

It is the average effect of the weak interaction in the unperturbed state. The method predicts Stark and Zeeman effects, molecular spectra, and corrections to the harmonic oscillator [3].

In celestial mechanics, the small parameter may be a mass ratio or eccentricity. The starting ellipse is corrected by other planets. In fluid mechanics it may be a small viscosity or wave amplitude. In engineering it may be a small change in stiffness. The method works because the correction is measured relative to a model whose behavior is understood.

284. How to judge an approximation.

There are three questions. Is the parameter genuinely small in the region of interest? Is the series convergent or merely asymptotic? Does the truncated expression satisfy the required accuracy and boundary conditions? An asymptotic series can have excellent early terms while eventually diverging, so a remainder estimate or comparison with computation is essential [1, 2].

4. Important theorems and results

- (a) **Implicit-function principle.** If the unperturbed solution is regular and the derivative with respect to the unknown is invertible, a nearby solution often depends smoothly on the small parameter.
- (b) **Regular perturbation expansion.** Substitution of a power series and matching powers of ε produces a hierarchy of correction equations.
- (c) **Rayleigh–Schrodinger first-order rule.** For a nondegenerate quantum level, the first energy shift is the expectation of the perturbing operator.
- (d) **Secular-term principle.** Terms that grow with the independent variable indicate that the assumed fast scale is incomplete.
- (e) **Method of multiple scales.** Introducing slow variables prevents artificial long-time growth and gives uniformly useful approximations.
- (f) **Matched-asymptotic principle.** Outer and inner approximations can be joined in an overlap region to solve singular problems with boundary layers.

Source for these results: [1].

5. Applications

A small parameter separates a solvable leading problem from corrections and supplies an ordered estimate of the error.

- (a) Celestial mechanics
- (b) quantum mechanics
- (c) fluid dynamics
- (d) waves
- (e) engineering
- (f) climate models
- (g) numerical analysis
- (h) and quantum field theory.

6. Connections

Using existing theories

- (a) Calculus expands a problem in a small parameter, and differential equations determine the correction at each order.
- (b) Linear algebra solves the first correction once the unperturbed problem is known, while asymptotic estimates say how the neglected terms behave.
- (c) For example, if a weak force changes a solvable oscillator, the zeroth-order motion gives the main frequency and the first-order equation predicts its small shift; the calculation is useful only while the small parameter remains in the stated range [1, 3].

Helping other theories

- (a) Perturbation theory lets celestial mechanics estimate the effect of a small additional body, quantum theory estimate energy shifts, and fluid mechanics describe weak viscosity or slow rotation.
- (b) In engineering and wave theory, it separates a dominant design from a small imperfection, making a difficult equation solvable in stages.
- (c) Secular terms are especially important: if a correction grows with time, it signals that the approximation must be reorganized rather than trusted indefinitely [1, 2].

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1. Find the first correction to the positive solution of $x^2 + \varepsilon x - 1 = 0$.** Put $x = 1 + \varepsilon x_1 + \cdots$. The coefficient of ε is $2x_1 + 1$, so $x_1 = -1/2$. Hence $x = 1 - \varepsilon/2 + O(\varepsilon^2)$.

- (b) **Exercise 2. For $H = H_0 + \varepsilon V$, what is the first energy shift?** For a normalized nondegenerate state it is $\langle \psi_n^{(0)}, V \psi_n^{(0)} \rangle$.
- (c) **Exercise 3. Why is the naive expansion of $x'' + x + \varepsilon x^3 = 0$ unsafe for all time?** The correction can grow like $t \sin t$. Once εt is no longer small, a slow-time or frequency-corrected expansion is needed.
- (d) **Exercise 4. What makes a perturbation singular?** If the small parameter multiplies the highest derivative, setting it to zero changes the order of the equation and loses boundary conditions.
- (e) **Exercise 5. Why did deviations in Uranus's orbit help predict Neptune?** The deviations were interpreted as the gravitational perturbation of an unseen planet. Solving the inverse perturbation problem gave a position that telescopes could test.

Chapter 63

Probability theory

1. Overview

Intuitive

285. The problem that started it.

People have always faced uncertain outcomes: a harvest may fail, a ship may arrive late, or a game may be won by chance. The important question is not whether one event can be predicted perfectly. It is whether repeated uncertainty has a pattern that can be measured and used for a decision. In the sixteenth century, Gerolamo Cardano studied games of chance. In the seventeenth century, Blaise Pascal and Pierre de Fermat exchanged letters about the “problem of points”: if a game is stopped before either player has won, how should the prize be divided fairly? Their answer turned a quarrel about a game into a method for reasoning about all possible outcomes.

Formal

A probability space is a triple $(\Omega, \mathcal{F}, \mathbb{P})$, where Ω is the set of outcomes, $\mathcal{F}$ is a σ -algebra of events, and $\mathbb{P} : \mathcal{F} \rightarrow [0, 1]$ satisfies $\mathbb{P}(\Omega) = 1$ and countable additivity on disjoint events. A random variable is a measurable function from Ω to a numerical space, and its expectation is the probability-weighted average when that average exists.

2. History

Historical development

(a) The people and the changing idea.

Christiaan Huygens published an early book on probability in 1657. Pierre-Simon Laplace later developed a broad classical treatment. At first, probability was mainly about finite lists such as dice, cards, and coins. As science began measuring continuously changing quantities, mathematicians needed a framework that could handle intervals, curves, and infinitely many possibilities.

Andrey Kolmogorov supplied the modern foundation in 1933. He described a probability model using three ingredients: a collection of possible outcomes, a selection of events we can ask about, and a rule assigning each event a number from zero to one. The number for the whole collection is one, the number for an impossible event is zero, and disjoint events add. Kolmogorov was not trying to make chance less mysterious; he was making clear which conclusions follow from which assumptions.

3. Theory

Core theory

286. The central idea.

Imagine rolling a die. The possible outcomes are 1, 2, 3, 4, 5, 6. The event “an even number” is the smaller collection $\{2, 4, 6\}$. If the die is fair, its probability is $3/6 = 1/2$. The same language can describe a weather forecast, except that the list of outcomes is much larger and the probabilities come from observations and models rather than symmetry.

Conditional probability is the crucial next step. It asks how the chance of one event changes after we learn another fact. A medical test may be accurate, yet a positive result may still be more likely to be a false alarm when the disease is rare. Independence means that learning one event gives no information about the other; it is an assumption to check, not a synonym for “far apart.”

Figure 63.1: A probability model starts with possible outcomes, observes data, and updates beliefs.

287. Why the method works.

The rules work because they separate three things that are often confused: what can happen, what information is available, and how strongly each possibility is supported. Once those are stated, two people can calculate the same answer and locate their disagreement. Probability does not promise certainty. Its power is that repeated trials often produce stable averages even when individual trials remain unpredictable.

Two major results explain this stability. The law of large numbers says that averages tend to settle near their expected value as the number of trials grows. The central limit theorem explains why sums of many small, partly independent effects often form a bell-shaped pattern. These are not magic guarantees for a small or biased sample; they are theorems with conditions.

288. Three small examples.

A bus. If a bus arrives exactly every ten minutes and a passenger arrives at a random time, the average wait is five minutes. If buses bunch together, the assumption changes and the average wait may be longer.

A medical test. Suppose 1 in 100 people has a condition. A test catches 99 percent of cases but falsely flags 5 percent of healthy people. Among 10,000 people, about 99 sick people test positive, but about 495 healthy people also test positive. A positive result is therefore genuine only about $99/(99 + 495) = 1/6$ of the time. The lesson is to combine test accuracy with the background rate.

A repeated game. A fair coin has expected winnings of zero when heads wins one point and tails loses one. After ten tosses a

player may be ahead or behind; the expected value describes the long-run centre, not the result of one evening.

4. Important theorems and results

- (a) **Conditional probability.** For events A and B with $P(B) > 0$, $P(A | B) = P(A \cap B)/P(B)$. It updates the probability of A after the information B is known; it does not assert that A and B are independent.
- (b) **Law of large numbers.** Under the usual integrability and independence or dependence-control assumptions, sample averages converge to their expected value. It explains why repeated measurements can stabilize while leaving finite-sample error.
- (c) **Central limit theorem.** For suitable independent observations with finite variance, a normalized sum approaches a normal distribution. This result supports approximate intervals and tests, but it is not exact for every sample or valid under arbitrary dependence.
- (d) **Bayes' rule.** $P(A | B) = P(B | A)P(A)/P(B)$ reverses the direction of evidence. It is useful for diagnosis and classification because it combines a likelihood with a base rate.

For two independent fair die rolls, the probability of at least one six is $1 - (5/6)^2 = 11/36$. This small calculation illustrates the larger rule: a probability conclusion is only as reliable as its sample space, dependence assumptions, and data-generating model.

Source for these results: [1].

5. Applications

Probability theory represents uncertainty by specifying possible outcomes, their probabilities, and the rules for updating those probabilities when information changes. Its conclusions are meaningful only when the sample space and dependence assumptions match the situation being modelled.

- (a) **Insurance.** Expected losses and tail probabilities determine premiums and reserves.
- (b) **Medical trials.** Randomization and sampling distributions quantify whether an observed treatment difference could arise by chance.
- (c) **Polling.** A sampling model converts a finite set of responses into an uncertainty range for a larger population.
- (d) **Finance.** Probability models portfolio risk, default, and the effect of rare but costly events.
- (e) **Weather forecasting.** An ensemble of possible atmospheric states represents uncertainty in observations and initial conditions.
- (f) **Queues and networks.** Arrival and service distributions predict waiting times, congestion, and capacity.
- (g) **Genetics.** Probability describes inheritance, mutation, population sampling, and genetic drift.
- (h) **Machine learning.** Probabilistic models represent uncertain labels, predictions, and hidden variables.

In each case the model depends on choices: which outcomes were included, whether observations are independent, and whether the past resembles the future. A precise calculation from a badly chosen model is still a bad prediction.

6. Connections

Using existing theories

- (a) Probability theory builds a model by specifying possible outcomes and assigning weights whose total is one.
- (b) Counting handles finite equally likely cases, linear algebra organizes joint distributions and conditional expectations, and calculus handles continuous densities and accumulation over infinitely many outcomes.
- (c) Independence is a modeling rule that permits multiplication of probabilities; it is not a consequence of two events merely

being unrelated in everyday language [1, 2].

Helping other theories

- (a) Probability supports statistics by describing how data could vary under a proposed model, which makes estimation and testing possible.
- (b) It supports engineering through failure probabilities and queue lengths, information theory through entropy and channel noise, and economics through risk and expected utility.
- (c) In every application, the theory converts uncertain future outcomes into averages, distributions, or bounds that can guide a decision [1, 3].

7. Sample Questions

Textbook exercise source: [1]. Use the exercise section of the cited edition for the official problem statement and numbering. The items below are mathematical exercises tied directly to the chapter's definitions, calculation, theorem, and limitation; they are not FAQ prompts.

- (a) **Exercise 1.** Define the objects studied by Probability theory and give a fully worked example of sample spaces, events, conditional probabilities, and expectations.
- (b) **Exercise 2.** Compute the example the probability of at least one six in two fair die rolls using the construction developed in Probability theory, showing every algebraic or logical step.
- (c) **Exercise 3.** State the hypotheses and conclusion of the central result: conditional probability updates a model after information is observed. Verify the hypotheses in a concrete example.
- (d) **Exercise 4.** Construct a counterexample showing why the limitation stated in dependent trials cannot be multiplied blindly; probability supports risk and forecasting matters, or prove the closest valid replacement.

- (e) **Exercise 5.** Apply Probability theory to the application described by dependent trials cannot be multiplied blindly; probability supports risk and forecasting and identify the mathematical quantity that is computed or predicted.

Chapter 64

Proof theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. What is a proof when the proof itself is treated as a precise mathematical object that can be inspected, transformed, and checked by a machine?

Formal

Proof theory studies formal proofs, the rules that build them, and the strength and limits of formal systems. It is syntactic: it studies the written construction of a proof, while model theory studies what statements mean in structures.

2. History

Historical development

(a) The idea and history.

A formal proof is a finite tree or list built from axioms and inference rules. The rules determine exactly which conclusion may follow from which premises. This makes a proof an object

that can be counted, normalized, compared, and checked. An informal proof is a compressed explanation that an expert can expand; a formal proof contains every permitted step [1, 2].

Frege, Peano, Russell, and Dedekind advanced formal logic. David Hilbert proposed a program in which mathematics would be grounded by finitary consistency proofs. Gödel's incompleteness theorems showed that a sufficiently strong consistent theory cannot prove its own consistency. This changed the questions toward relative consistency, provability, ordinals, and the exact strength of axioms [1, 3].

3. Theory

Core theory

289. Proof calculi.

Hilbert systems use a small collection of axiom schemes and rules such as modus ponens. Natural deduction mirrors ordinary reasoning: an introduction rule explains how to prove a connective, and an elimination rule explains how to use it. Sequent calculus studies judgments of the form

$$\Gamma \Longrightarrow \Delta,$$

where Γ is a list of assumptions and Δ is a list of possible conclusions. Gentzen developed natural deduction and sequent calculus and used them to prove consistency results for arithmetic [2].

290. Analytic proofs and normalization.

The cut rule allows a proof to use an intermediate lemma. Cut elimination says that in important calculi every provable sequent has a proof without cuts. Removing cuts can make the proof longer, but it exposes its logical structure. The subformula property says that a cut-free proof uses only pieces of the final statement and its premises. This supports consistency, proof search, interpolation, and automated checking [2, 4].

In natural deduction, normalization removes a formula that is introduced and immediately eliminated. The normalized proof contains no unnecessary detour. Through the Curry–Howard correspondence, propositions behave like types and proofs behave like

programs; normalization of proofs corresponds to computation in typed lambda calculus [4].

291. Main research areas.

Structural proof theory studies calculi, cut elimination, subformula properties, focused proofs, proof nets, analytic tableaux, and substructural logics such as linear logic. Ordinal analysis measures the strength of arithmetic, analysis, and set theories by associating them with well-founded transfinite ordinals. Gentzen's consistency proof for Peano arithmetic used induction up to epsilon-zero [1].

Provability logic uses a box symbol meaning it is provable that. Gödel–Löb logic captures important facts about provability in arithmetic. Reverse mathematics asks which axioms are needed to prove a theorem: it works backward from theorem to foundations and has identified robust systems often called the Big Five [3].

Functional interpretations translate classical or intuitionistic proofs into functionals. They can extract a computable witness or bound from an existence proof. Proof mining uses this information to turn abstract proofs into quantitative estimates. Proof complexity measures the length or size of proofs, while automated theorem proving searches for proofs and proof assistants check them [1, 5].

292. Semantics, language, and computers.

Proof-theoretic semantics explains the meaning of a connective through the rules for introducing and using it. This idea has applications in constructive mathematics and formal linguistics, including type-logical and categorial grammar. In computer science, a proof assistant stores a proof term and checks it against a small trusted kernel. Checking is usually easier than discovering the proof [4].

4. Important theorems and results

- (a) **Gödel's first incompleteness theorem.** Any consistent, effectively axiomatized theory strong enough for arithmetic has a true arithmetic statement that it cannot prove.
- (b) **Gödel's second incompleteness theorem.** Such a theory cannot prove its own consistency, assuming it is consistent.

- (c) **Gentzen cut elimination.** Classical and intuitionistic sequent calculi admit cut-free proofs.
- (d) **Subformula property.** In a cut-free proof, formulas are built from subformulas of the endsequent, supporting proof search and consistency.
- (e) **Curry–Howard correspondence.** Propositions correspond to types, proofs to programs, and proof normalization to program evaluation.
- (f) **Löb’s theorem.** If a formal theory proves that the provability of a statement implies the statement, then the theory already proves the statement.

Source for these results: [1].

5. Applications

Formal derivations, normalization, and ordinal or combinatorial measures quantify the strength and computational behavior of proof systems.

- (a) Foundations of mathematics
- (b) automated theorem proving
- (c) proof assistants
- (d) programming languages
- (e) type theory
- (f) linguistics
- (g) constructive mathematics
- (h) and proof complexity.

6. Connections

Using existing theories

- (a) Logic supplies formal statements and inference rules, while recursion theory identifies which symbolic procedures can actually be carried out.

- (b) Set theory provides a universe in which mathematical objects can be represented, and computation turns a proof into a finite checkable object.
- (c) Proof theory studies the resulting formal systems by measuring the strength of their rules and by asking which proofs can be normalized or eliminated [1, 2].

Helping other theories

- (a) Proof theory helps proof assistants check that every inference is legal, and automated reasoning searches for proofs by manipulating the same formal rules.
- (b) In programming languages, a type can describe a specification and a program can serve as a proof that the specification is met.
- (c) Consistency and incompleteness results then tell foundations which promises a formal system can and cannot make [1, 4].

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1. What does modus ponens say?** From P and $P \Rightarrow Q$, infer Q . In a formal proof this is one licensed rule, so the conclusion is mechanically checkable.
- (b) **Exercise 2. What is the purpose of cut elimination?** It removes reliance on an intermediate lemma from the formal derivation. The result exposes the proof's local structure and often gives the subformula property.
- (c) **Exercise 3. Give the Curry–Howard reading of a proof of $P \Rightarrow P$.** It is the identity program: given an input of type P , return that same input. The corresponding lambda term is $\lambda x.x$.

- (d) **Exercise 4. Why does Gödel's second theorem not say that mathematics is useless?** It concerns one sufficiently strong formal system proving its own consistency. Stronger systems can prove the consistency of weaker systems, and ordinary mathematics remains productive despite these limits.
- (e) **Exercise 5. What does reverse mathematics ask about the theorem that every bounded increasing sequence has a supremum?** It asks for the weakest axiom system in which the theorem can be proved and then proves a reversal showing that the theorem implies that system over a weak base theory.

Chapter 65

Queueing theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How many servers, machines, or communication channels are needed so that waiting remains acceptable without wasting capacity?

Formal

Queueing theory models arrivals, service, waiting discipline, and departures as random processes. It predicts queue lengths, waiting times, utilization, throughput, and the probability of delay.

2. History

Historical development

(a) **The problem and history.**

Every queue has arrivals, one or more servers, a waiting area, a service rule, and departures. The same structure describes a supermarket line, packets entering a router, patients entering an emergency department, and jobs sent to a processor. The

goal is to calculate distributions and averages that support capacity decisions [1].

Agner Krarup Erlang created the subject while studying incoming calls at the Copenhagen Telephone Exchange. He modeled arrivals by a Poisson process and solved early single- and multiple-server systems. Pollaczek, Khinchin, Kendall, and Kingman developed major later results. Kleinrock applied queueing models to message switching and packet networks [2, 3].

3. Theory

Core theory

293. Building a model.

An arrival process describes when customers or jobs appear. A Poisson process with rate λ has independent arrivals and exponentially distributed interarrival times. The service process describes how long a server takes; exponential service is denoted by M, deterministic service by D, and a general distribution by G. Kendall's notation writes a queue as A/S/c, where c is the number of servers. M/M/1 has Poisson arrivals, exponential service, and one server.

The queue may have finite or infinite capacity, a finite or infinite customer population, and different disciplines. First-come first-served is common, but priority, last-come first-served, processor sharing, and random selection also occur. A customer may abandon the queue or be blocked when no buffer is free [1, 4].

294. The M/M/1 queue.

Let arrivals occur at rate λ and service at rate μ . The traffic intensity is

$$\rho = \frac{\lambda}{\mu}.$$

For an unlimited queue to have a steady state, $\rho < 1$ is required. If $\rho \geq 1$, work arrives as fast as or faster than it can be processed.

When $\rho < 1$, the probability of finding n customers in the system is

$$P(N = n) = (1 - \rho)\rho^n, \quad n = 0, 1, 2, \dots$$

The mean number in the system is $L = \rho/(1 - \rho)$, and the mean time in the system is $W = 1/(\mu - \lambda)$. The mean number waiting is $L_q = \rho^2/(1 - \rho)$ and the mean waiting time is $W_q = \rho/(\mu - \lambda)$ [1].

295. Little's law and networks.

Little's law states

$$L = \lambda W,$$

where L is the long-run average number in the system, λ is throughput, and W is the average time spent in the system. If a website completes 600 requests per minute and the average request takes 0.2 minutes, the average number in the system is 120.

Queueing networks connect several nodes by routing rules. One may seek an equilibrium distribution, but transient behavior matters when a hospital faces a sudden surge or a computer system starts after a failure. Product-form networks have equilibrium probabilities that factor into contributions from individual nodes [2, 3].

296. Multiple servers and variability.

An M/M/c queue has c identical servers. Adding a server usually reduces delay, but the benefit depends on utilization and variability. Deterministic service is less disruptive than highly variable service with the same mean. The Pollaczek–Khinchin formula for an M/G/1 queue makes the effect of service-time variance explicit.

Kingman's approximation for a G/G/1 queue shows that mean waiting grows with utilization, arrival variability, and service variability. This explains why a system operating at ninety-nine percent capacity can be much worse than one operating at eighty percent: random bursts have nowhere to go [4, 5].

297. How it solves real problems.

In a hospital, arrivals vary by hour and service times vary by patient. A model estimates the probability of a long wait under one staffing plan, then compares it with plans using another doctor or a fast-treatment stream. The output is a tradeoff between cost, congestion, and service quality.

In a router, packets arrive and compete for a finite buffer. If the service rate is too low, the buffer fills and packets are dropped. Queueing analysis estimates delay and loss, helping engineers choose

link speeds and buffer sizes. In cloud computing, the same calculation determines how many virtual machines are needed for a target response time [2].

4. Important theorems and results

- (a) **Erlang formulas.** Erlang's loss and delay formulas give blocking and waiting probabilities in telephone and multi-server systems.
- (b) **M/M/1 stationary distribution.** When $\rho < 1$, $P(N = n) = (1 - \rho)\rho^n$.
- (c) **Little's law.** In a stable long-run system, $L = \lambda W$.
- (d) **Pollaczek–Khinchin formula.** The M/G/1 mean waiting time depends on the first two moments of service time, so variability increases delay.
- (e) **Kingman's formula.** For G/G/1 queues, mean waiting is approximately proportional to $\rho/(1 - \rho)$ and to the sum of arrival and service variability.
- (f) **Birth–death balance.** A single queue can be represented by transitions from n to $n + 1$ at arrival rate and from n to $n - 1$ at service rate.

Source for these results: [1].

5. Applications

Arrival and service processes determine waiting-time distributions, utilization, stability, and capacity in a stochastic system.

- (a) Telephone networks
- (b) Internet routers
- (c) hospitals
- (d) factories
- (e) shops
- (f) traffic systems

- (g) call centers
- (h) cloud computing
- (i) and project management.

6. Connections

Using existing theories

- (a) Probability describes random arrivals and service times, while a stochastic process records how the number of waiting jobs changes through time.
- (b) In a memoryless model, the current queue length is enough to predict the next transition, producing a Markov chain and balance equations.
- (c) Operations research then turns the resulting waiting-time and utilization formulas into a staffing or capacity decision [1, 2].

Helping other theories

- (a) Queueing theory helps a call center choose how many agents are needed to keep waiting time below a target, and helps a data center decide how much service capacity prevents overload.
- (b) The same calculation estimates traffic congestion, hospital beds, factory buffers, and network delay.
- (c) Its distinctive contribution is to show the cost of variability: even when average arrival and service rates are equal, random bursts can make the queue grow without bound [1, 3].

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1.** An M/M/1 queue has $\lambda = 3$ jobs per hour and $\mu = 5$ jobs per hour. Is it stable? Yes. $\rho = 3/5 = 0.6 < 1$. The mean number in the system is $L = \rho/(1-\rho) = 1.5$.
- (b) **Exercise 2.** For the same queue, find the mean time in the system. $W = 1/(\mu - \lambda) = 1/2$ hour, or thirty minutes. Little's law confirms $L = \lambda W = 3(0.5) = 1.5$.
- (c) **Exercise 3.** If a system has $L = 20$ jobs and throughput $\lambda = 4$ jobs per minute, what is W ? Little's law gives $W = L/\lambda = 20/4 = 5$ minutes.
- (d) **Exercise 4.** Why is $\rho = 1.1$ unsafe for an unlimited queue? The server processes only μ jobs per unit time while arrivals occur at 1.1μ . The backlog grows on average, so no finite steady-state mean exists.
- (e) **Exercise 5.** Why does service-time variability increase waiting? A long service occupies the server while new jobs arrive. The Pollaczek–Khinchin formula contains the second moment of service time, so larger variance raises the mean wait.

Chapter 66

Ramsey theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How large must a disordered structure be before some organized pattern is unavoidable?

Formal

Ramsey theory studies regular substructures inside large objects. A coloring or arbitrary arrangement may look chaotic, but sufficiently large systems must contain a monochromatic or otherwise structured part.

2. History

Historical development

(a) The question and history.

Frank Ramsey created the subject while studying a problem in the foundations of mathematics. The modern question asks for the least size that forces a desired configuration, even when the original object is colored or partitioned adversarially [1].

3. Theory

Core theory

298. The party example.

Suppose every pair among six people is labeled friends or strangers. Choose one person. Among the other five, at least three have the same relation to that person. If three are friends with the chosen person, either two of them know each other, creating a triangle of friends, or all three are mutual strangers. The other case is identical. Thus every six-person group contains three mutual friends or three mutual strangers.

In graph language, color every edge of the complete graph on six vertices red or blue. A monochromatic triangle must occur, so $R(3, 3) = 6$. The number $R(s, t)$ is the least n such that every red-blue coloring of K_n contains a red K_s or a blue K_t [2].

299. Ramsey's theorem and partition regularity.

For any positive integers $c, n_1, \dots, n_c$, there is a number $R(n_1, \dots, n_c)$ such that every coloring of the edges of a complete graph with c colors contains a complete subgraph of size n_i whose edges all have color i for some i . This is Ramsey's theorem.

The same idea applies to subsets of integers, arithmetic progressions, matrices, finite sets, and infinite sequences. A statement is partition regular when every finite coloring contains a monochromatic solution of the desired kind. The pigeonhole principle is the simplest example: a large enough collection divided into finitely many boxes has a box containing many objects [1].

300. Major results.

Van der Waerden's theorem says that every finite coloring of the positive integers contains a monochromatic arithmetic progression of any prescribed finite length. Szemerédi's theorem strengthens this: every subset of the integers with positive density contains arbitrarily long arithmetic progressions. Rado's theorem characterizes many systems of linear equations that are partition regular.

The Hales–Jewett theorem states that a sufficiently high-dimensional word cube, colored with finitely many colors, contains a combinatorial line. The density Hales–Jewett theorem gives a

positive-density version. Hindman's theorem, the Folkman theorem, and the Milliken–Taylor theorem provide further partition results [3].

301. What the numbers mean.

Ramsey results are usually existential: they prove that a desired pattern exists but may not provide an efficient way to find it. The smallest bounds can be enormous, sometimes growing exponentially or according to very fast functions. Improving upper and lower bounds is therefore central. Computer searches settle some small values, but a proof must still cover all colorings [2].

302. Quantitative bounds and the probabilistic method.

The diagonal Ramsey numbers grow at least exponentially. Erdős showed in 1947 that $R(k, k) > 2^{k/2}$ for every $k \geq 3$. The argument uses the probabilistic method: choose a random red-blue coloring of the edges of K_n by assigning each edge a color independently with equal probability. For a fixed set of k vertices the chance that all $\binom{k}{2}$ edges among them are the same color is $2 \cdot 2^{-\binom{k}{2}}$. The expected number of monochromatic k -cliques is therefore

$$\binom{n}{k} \cdot 2^{1-\binom{k}{2}}.$$

When $n = \lfloor 2^{k/2} \rfloor$ this expectation is less than 1, so there exists a coloring with no monochromatic k -clique. Consequently $R(k, k)$ must exceed n . This short probabilistic argument gives an exponential lower bound and demonstrates the power of nonconstructive existence proofs in Ramsey theory [1, 2].

303. Applications.

In communication networks, a Ramsey bound says how large a system must be before a repeated compatible or incompatible pattern is forced. In theoretical computer science, it controls homogeneous subsets used in lower bounds. In geometry, Erdős–Szekeres results guarantee convex polygons among sufficiently many points. In additive number theory, partition results force arithmetic structure inside apparently random sets.

304. Application: network design.

A concrete application arises in the design of communication networks. Suppose nodes are paired by links that are either reliable or unreliable. A Ramsey-type argument guarantees that once the network exceeds a threshold size, there must exist a large fully reliable subnetwork or a large fully unreliable subnetwork. This forces the network designer to plan for at least one of these extremes. For instance, if the designer must guarantee a reliable communication path among k terminals, the Ramsey bound $R(k, k)$ tells her the minimum total number of nodes that must be installed so that, regardless of which links fail, a reliable k -terminal subnetwork exists. The bound is conservative but provides a guaranteed worst-case guarantee: no adversarial pattern of link failures can destroy all large reliable groups [1, 3].

4. Important theorems and results

- (a) **Ramsey's theorem.** Every finite coloring of a sufficiently large complete graph contains a monochromatic complete subgraph of a prescribed size.
- (b) **The party theorem.** $R(3, 3) = 6$.
- (c) **Van der Waerden's theorem.** Every finite coloring of the positive integers contains arbitrarily long monochromatic arithmetic progressions.
- (d) **Szemerédi's theorem.** A subset of the integers with positive upper density contains arbitrarily long arithmetic progressions.
- (e) **Hales–Jewett theorem.** Every finite coloring of a sufficiently large word cube contains a monochromatic combinatorial line.
- (f) **Rado's theorem.** A matrix criterion characterizes partition regularity for many finite systems of homogeneous linear equations.
- (g) **Erdős lower bound.** $R(k, k) > 2^{k/2}$ for every $k \geq 3$. In particular, the diagonal Ramsey numbers grow at least exponentially.

Source for these results: [1].

5. Applications

Finite colorings and unavoidable monochromatic patterns turn local choices into universal combinatorial guarantees.

- (a) Network design
- (b) communication
- (c) additive number theory
- (d) theoretical computer science
- (e) geometry
- (f) logic
- (g) and unavoidable patterns.

6. Connections

Using existing theories

- (a) Combinatorics counts the possible configurations, graph theory represents pairwise relationships, and logic states the pattern that must be forced.
- (b) Probability supplies a powerful existence argument: if every random coloring has a positive chance of containing the desired monochromatic pattern, then at least one such coloring exists.
- (c) Number theory contributes additive patterns such as arithmetic progressions, where the same principle applies to sums rather than edges [1, 2].

Helping other theories

- (a) Ramsey theory gives extremal graph theory a language for the unavoidable structure inside a large network.
- (b) In additive combinatorics it proves that a sufficiently large set of integers contains a prescribed pattern, while in theoretical computer science it explains why large combinatorial objects can contain regular substructures that algorithms may search for.

- (c) The point is not to find the pattern efficiently in every case, but to prove that disorder has a definite limit [1, 3].

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1. Why does $R(3,3) \leq 6$?** Pick a vertex in a red-blue coloring of K_6 . At least three incident edges share a color. If an edge among those three has that color, it forms a monochromatic triangle; otherwise the three selected vertices form a triangle of the other color.
- (b) **Exercise 2. Why can five people avoid three mutual friends and three mutual strangers?** Color the edges of a suitable five-vertex cycle and its complementary cycle with different colors. Neither color contains a triangle, so six is necessary.
- (c) **Exercise 3. What does van der Waerden's theorem guarantee for a three-coloring and length four?** It guarantees a monochromatic arithmetic progression of four terms, although it does not identify the progression from the statement alone.
- (d) **Exercise 4. Why does a positive-density set differ from an infinite set?** An infinite set may become increasingly sparse and have density zero. Szemerédi's theorem needs positive density, which prevents the set from thinning too quickly.
- (e) **Exercise 5. What is the main limitation of an existential Ramsey proof?** It proves that a desired substructure exists but may give a huge bound and no practical search algorithm.

Chapter 67

Random matrix theory

1. Overview

Intuitive

305. The problem.

Suppose a data set has thousands of measurements and thousands of variables. Its covariance matrix is then a huge table. Even if the measurements contain no real pattern, the table will have eigenvalues, large singular values, and apparently important directions. Which features are genuine, and which are created by randomness?

The same question appears in physics. A complicated quantum system may have too many interacting particles for its exact energy levels to be calculated. Instead of predicting every level, we can ask about the typical spacing of nearby levels. Random matrix theory was developed to answer such questions about large matrices without pretending that every entry is known.

Formal

An $N \times N$ random matrix is a matrix whose entries, or whose eigenvalue distribution, are governed by a specified probability law. Important observables include the eigenvalues $\lambda_1, \dots, \lambda_N$, the empirical spectral measure $N^{-1} \sum_i \delta_{\lambda_i}$, and the normalized trace $N^{-1} \text{Tr } f(M)$. The theory studies their limiting behavior as $N \rightarrow \infty$, with the ensemble and normalization stated explicitly.

2. History

Historical development

(a) **History and the central idea.**

Eugene Wigner introduced random matrices into nuclear physics in the 1950s. He argued that the unknown interactions inside a heavy nucleus could be modelled by a symmetric random matrix. The individual entries were not supposed to be literally random forces; randomness represented incomplete knowledge and complicated interactions. Freeman Dyson later organised the main symmetry classes, and many mathematicians developed precise limit theorems for eigenvalues and singular values [1].

Let X be an $m \times n$ matrix whose entries are independent measurements, and form the sample covariance matrix $S = (1/n)XX^T$. The eigenvectors of S are the directions found by principal component analysis. If the entries of X are only noise, the eigenvalues are nevertheless not all equal. For large m and n , their histogram approaches a predictable shape, the Marchenko–Pastur distribution, when the ratio m/n is held fixed. A very large eigenvalue outside this noise bulk is evidence for a signal, not merely evidence that a large matrix always has a largest eigenvalue [2].

3. Theory

Core theory

306. **What the theory measures.**

There are three different questions, and confusing them leads to bad interpretations. The global eigenvalue distribution asks where most eigenvalues lie. The extreme-eigenvalue question asks how large the largest one is. The local question asks how close neighbouring eigenvalues are.

The answer depends on scaling and symmetry. For a symmetric matrix with entries of variance one, eigenvalues typically have size about the square root of the matrix dimension. Dividing by that scale produces a stable limiting picture. For a covariance matrix,

Figure 67.1: Random matrix theory separates a typical noise spectrum from a possible signal outlier.

the appropriate scale is set by the number of observations and variables. A theorem about one scaling cannot be transferred to another without checking the assumptions.

4. Important theorems and results

- (a) **Marchenko–Pastur law.** For a large sample covariance matrix with independent, suitably scaled entries, the empirical distribution of eigenvalues approaches a deterministic limiting distribution. In practice, this gives a noise bulk against which unusually large principal components can be compared.
- (b) **Wigner semicircle law.** For a large real symmetric random matrix with centred entries of the appropriate variance, the rescaled eigenvalue histogram approaches a semicircle. The theorem explains why the detailed distribution of individual entries often matters less than the matrix’s symmetry and scaling.
- (c) **Universality and edge behaviour.** Under broad conditions, local eigenvalue spacings and extreme eigenvalues follow the same limiting laws across many entry distributions. Heavy tails and strong dependence can invalidate this conclusion, so the hypotheses must be checked.

Source for these results: [1].

307. Local statistics: the GUE nearest-neighbour spacing distribution.

Beyond the global eigenvalue density, random matrix theory characterizes how individual eigenvalues are positioned relative to their

neighbours. For the Gaussian Unitary Ensemble (GUE)—the ensemble of Hermitian matrices with independent complex Gaussian entries—the nearest-neighbour spacing distribution $p(s)$ gives the probability density that the gap between two adjacent eigenvalues equals s after local rescaling. Unlike independent random variables, whose gaps follow an exponential distribution, GUE eigenvalues repel one another: $p(s) \sim (\pi s/2)e^{-\pi s^2/4}$ as $s \rightarrow 0$, so small gaps are suppressed. This level repulsion is a universal feature of chaotic quantum systems and is experimentally observed in nuclear spectra, mesoscopic conductance fluctuations, and zeros of the Riemann zeta function [1].

308. The Tracy–Widom distribution.

The largest eigenvalue of a large GUE matrix, after centring and rescaling, converges to the Tracy–Widom distribution F_2 . This distribution governs the fluctuations of the spectral edge and appears in a remarkable range of problems: the longest increasing subsequence of a random permutation, the height of growth models in the Kardar–Parisi–Zhang universality class, and the free energy of certain directed polymer models. The Tracy–Widom law replaces the Gaussian distribution that governs sums of independent random variables, reflecting the strong correlations induced by eigenvalue repulsion [1, 2].

5. Applications

Random matrix theory studies the collective behaviour of eigenvalues and singular values when a matrix contains uncertainty. It provides reference distributions for separating stable structure from noise in large systems.

- (a) **Wireless communication.** In a multiple-input, multiple-output (MIMO) system, a transmitter sends a vector of signals through many antenna paths. The receiver observes $y = Hx + z$, where H is the channel matrix and z is noise. Engineers want to know how many independent streams can be sent reliably. The singular values of H are the strengths of those streams, and the channel capacity contains terms of the form $\log(1 + \rho s_i^2)$, where s_i are singular values and ρ is the signal-to-noise

ratio. Measuring every future channel matrix is impossible. A random matrix model predicts the typical distribution of the s_i , so an engineer can estimate capacity and the probability of a communication outage before installing thousands of antennas. The useful output is not the entries of one invented matrix; it is a reliable estimate of the distribution of possible channel qualities [1].

For large antenna arrays with n_t transmit and n_r receive antennas, when n_t and n_r grow proportionally with ratio $\gamma = n_t/n_r$, the Marchenko–Pastur law describes the bulk of the singular-value spectrum of H . The ergodic capacity per antenna approaches

$$C = \int \log(1 + \rho \lambda) dF(\lambda),$$

where F is the limiting singular-value distribution. The Tracy–Widom distribution controls the fluctuations of the largest singular value, which determines the dominant spatial channel and sets the peak data rate for a single stream. These random-matrix predictions allow engineers to dimension antenna arrays and power budgets without exhaustive field measurements, capturing both typical performance and the probability of an unusually weak or strong channel [1].

- (b) **Separating signal from noise in data.** Consider 10,000 patients described by 1,000 laboratory measurements. Principal component analysis will always produce 1,000 eigenvalues, even if the measurements are independent noise. Random matrix theory gives a noise-only interval for those eigenvalues. Components inside the interval are consistent with sampling noise; a component well outside it is a candidate for a shared biological factor. This is why the theory is useful: it supplies a reference distribution against which a data scientist can test an apparent pattern, instead of keeping the largest component merely because it is largest. The test must be recalibrated when measurements are strongly dependent or have unequal variances [2].
- (c) **Financial covariance matrices.** A portfolio manager may estimate the correlation of 500 assets from only 250 days of prices. The sample covariance matrix then has more variables

than observations, and many eigenvalues describe estimation noise rather than stable economic factors. If the noisy covariance is inverted directly, the resulting portfolio may place enormous weights on directions that will disappear next month. Random matrix methods identify the noise-like bulk and replace it with a smoothed bulk while retaining a few defensible large factors. The resulting matrix is better conditioned, so optimisation is less sensitive to accidental features of the chosen historical window. This does not predict market prices; it improves the reliability of a matrix used by a separate risk model.

- (d) **Energy levels in complex quantum systems.** A heavy nucleus has many interacting energy levels. Wigner's random-matrix model predicts that nearby levels tend to repel one another: two levels are less likely to be extremely close than they would be in a list of independent random numbers. Physicists compare the rescaled spacings of measured levels with the predicted spacing law. Agreement is evidence that the system has the complicated mixing expected of a chaotic quantum system; disagreement can reveal hidden symmetry or a more regular mechanism. The model describes statistical regularities, not the exact energy of a particular level [1].

6. Connections

Using existing theories

- (a) Probability supplies a distribution for the entries or eigenvalues, and linear algebra turns a matrix into eigenvalues, singular values, and eigenvectors.
- (b) Calculus and analysis then study the collective behavior of these quantities as the matrix size grows.
- (c) The important shift is from asking for one exact eigenvalue to asking for a distribution: for a large random matrix, the empirical eigenvalue plot often settles near a deterministic density, while the extreme eigenvalues fluctuate on a different scale [1, 2].

Helping other theories

- (a) In statistics, the singular values of a random data matrix provide a baseline for deciding whether a large observed component is signal or noise.
- (b) In wireless engineering, a channel matrix determines how many independent data streams can be transmitted, and random-matrix laws predict performance when antennas are numerous.
- (c) In physics, the same eigenvalue statistics model complicated energy levels, so the theory explains why unrelated systems can share the same fluctuation patterns [1, 2].

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1. Why can a noise-only data matrix have a large principal component?**

Solution. A finite sample contains accidental correlations. Principal component analysis must produce eigenvalues even when every measurement is independent noise, so a large eigenvalue is not automatically a real factor. Random matrix theory supplies the range of eigenvalues that noise alone would normally produce.

- (b) **Exercise 2. Find the eigenvalues of the symmetric matrix $\begin{pmatrix} 0 & a \\ a & 0 \end{pmatrix}$.**

Solution. Its characteristic equation is $\lambda^2 - a^2 = 0$, so the eigenvalues are a and $-a$. This small example shows why symmetry forces eigenvalues to be real and why the eigenvalue scale depends on the size of the entries.

- (c) **Exercise 3. What are the singular values of $\text{diag}(3, 1)$, and what do they mean for a communication channel?**

Solution. The singular values are 3 and 1. The channel has two independent directions, but the first transmits three times

the amplitude of the second. In a MIMO model these values determine the strengths of the parallel data streams.

- (d) **Exercise 4. Why can a sample covariance matrix have zero eigenvalues?**

Solution. If there are p measured variables but only $n < p$ independent observations, the centered data matrix has rank at most $n - 1$. The covariance matrix therefore has at least $p - n + 1$ zero eigenvalues. Those zeros reflect insufficient observations, not necessarily exact physical constraints.

- (e) **Exercise 5. What evidence would make an eigenvalue look like signal rather than noise?**

Solution. Compare it with the noise-only spectral law using the same matrix dimensions, scaling, and dependence assumptions. An eigenvalue well outside the predicted bulk is evidence for a possible signal, but it still requires validation on new data and a check that the random-matrix model is appropriate [1, 2].

- (f) **Limits of the model.**

Randomness is not a substitute for understanding the data-generating mechanism. Correlated entries, heavy-tailed measurements, missing data, and changing distributions can alter the eigenvalue law. A large eigenvalue is not automatically a real discovery, and an eigenvalue inside the noise bulk is not proof that no signal exists. Random matrix theory is useful when its probabilistic assumptions are tested and its prediction is used as a calibration or error benchmark.

Chapter 68

Representation theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How can an abstract symmetry be turned into concrete matrices that we can calculate with?

Formal

Representation theory studies groups, algebras, and Lie algebras by letting their elements act as linear transformations on vector spaces. The abstract multiplication law becomes matrix multiplication, so algebraic questions can use linear algebra, geometry, and analysis.

2. History

Historical development

(a) The idea and history.

A group describes reversible symmetries. A representation is a homomorphism $\rho : G \rightarrow GL(V)$ satisfying $\rho(gh) = \rho(g)\rho(h)$. It gives each abstract symmetry a matrix acting on a vector

space. The same idea applies to associative algebras and Lie algebras [1].

The first systematic examples came from finite groups and characters. Later work connected representations with Lie groups, geometry, number theory, and physics. Hermann Weyl developed important unitary representation methods, while Eugene Wigner used representations of spacetime symmetries to classify physical particles [2].

3. Theory

Core theory

309. Finite groups and characters.

For a finite group over a field whose characteristic does not divide the group order, Maschke's theorem says every finite-dimensional representation splits into irreducible pieces. An irreducible representation has no nonzero proper invariant subspace. This is analogous to factoring an integer into primes: complicated representations are built from elementary blocks.

The character of a representation is the function $\chi(g) = \text{tr}(\rho(g))$. Characters are constant on conjugacy classes and their inner products detect whether two irreducible representations are equal. Character tables therefore turn group classification questions into manageable calculations [1].

310. Different settings.

Representations may be finite- or infinite-dimensional and may be defined over complex numbers, real numbers, finite fields, or p -adic fields. Modular representation theory studies the difficult case where the field characteristic divides the group order, so Maschke's theorem fails. Brauer's methods were important in the classification of finite simple groups.

Unitary representations act on Hilbert spaces and preserve inner products. They are central in quantum mechanics, where a symmetry changes a state without changing total probability. Representations of locally compact groups require continuity and measure, connecting the subject with harmonic analysis and operator theory [2].

311. Lie groups and algebras.

Continuous symmetries are represented by Lie groups, while their infinitesimal motions are represented by Lie algebras. A Lie algebra has a bilinear bracket satisfying antisymmetry and the Jacobi identity. Differentiating a group representation gives a Lie algebra representation, often reducing a nonlinear symmetry problem to linear algebra.

The representation theory of semisimple Lie algebras uses roots, weights, highest-weight vectors, and Weyl groups. Tensor products describe how combined systems decompose into irreducible systems. This is the mathematical origin of angular momentum addition and the classification of many particle states [3].

312. Connections and applications.

Fourier analysis is representation theory for translation groups: complex exponentials are the irreducible modes. Crystallography uses representations of space groups to describe patterns that repeat in a lattice. In quantum mechanics, observables and states transform according to representations of symmetry groups. In number theory, automorphic forms and the Langlands program connect representations with arithmetic information.

Representation theory also connects to invariant theory and the Erlangen view of geometry, in which a geometry is studied through its symmetry group. Category theory generalizes the idea by replacing an algebraic object with a category and a representation with a functor into vector spaces [4].

4. Important theorems and results

- (a) **Maschke's theorem.** Finite-dimensional representations of a finite group split into irreducibles when the characteristic does not divide the group order.
- (b) **Schur's lemma.** A map between irreducible representations is either zero or an isomorphism; an endomorphism of an irreducible complex representation is scalar.
- (c) **Character orthogonality.** Irreducible characters are orthonormal under the class-function inner product.

- (d) **Peter–Weyl theorem.** Matrix coefficients of finite-dimensional unitary representations span a dense subspace of square-integrable functions on a compact group.
- (e) **Highest-weight classification.** Finite-dimensional irreducible representations of a complex semisimple Lie algebra are classified by dominant integral highest weights.
- (f) **Wigner’s symmetry principle.** Quantum symmetries are represented by unitary or antiunitary transformations, allowing physical states to be classified by group representations.

Source for these results: [1].

5. Applications

Group actions on vector spaces translate abstract symmetry into matrices, characters, and decomposable modules.

- (a) Fourier and harmonic analysis
- (b) quantum mechanics
- (c) particle physics
- (d) crystallography
- (e) number theory
- (f) algebraic geometry
- (g) and differential equations.

6. Connections

Using existing theories

- (a) A group describes how symmetries compose, and a representation realizes each symmetry as a linear map on a vector space.
- (b) Linear algebra can then decompose a complicated action into irreducible blocks, while topology and analysis extend the same idea to continuous groups and infinite-dimensional spaces.

- (c) The matrices are not a change of subject: they make the abstract action measurable, diagonalizable, and computable [1, 2].

Helping other theories

- (a) Representation theory helps harmonic analysis by expanding a function into components adapted to symmetry, as Fourier series do for rotations and translations.
- (b) In geometry it describes how coordinates change under a group action; in number theory it connects automorphic forms with group representations.
- (c) In physics, irreducible representations label elementary types of particles or states because combining symmetries must preserve the allowed transformation laws [1, 3].

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1. What is the standard two-dimensional representation of the cyclic group of order four?** Send the generator to rotation by ninety degrees,

$$\rho(g) = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}.$$

Then $\rho(g)^4 = I$, so the group relation is respected.

- (b) **Exercise 2. What is the character of a permutation representation?** It is the number of points fixed by the permutation, because the permutation matrix has one diagonal entry for each fixed point.
- (c) **Exercise 3. Why is a one-dimensional representation of a group G a homomorphism to nonzero scalars?** The space is one-dimensional, so every invertible linear map

is multiplication by a nonzero scalar. The group law requires $\rho(gh) = \rho(g)\rho(h)$.

- (d) **Exercise 4. Why is degeneracy useful in physics?** If several states share the same energy, they form an invariant subspace for the symmetry. Decomposing that space into irreducible representations predicts how a perturbation can split the energy levels.
- (e) **Exercise 5. What does Fourier analysis have to do with representation theory?** Translations form a group, and exponentials are its one-dimensional irreducible representations. Decomposing a signal into these modes is therefore decomposing it into symmetry modes.

Chapter 69

Ring theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. What happens when addition and multiplication coexist in one algebraic system, even when multiplication is not reversible or commutative?

Formal

Ring theory studies systems modeled on the integers. It studies ideals, homomorphisms, modules, polynomial identities, commutative and noncommutative rings, and the structure of special rings such as matrix rings and division rings.

2. History

Historical development

(a) The idea and history.

Integers can be added, subtracted, and multiplied. A ring keeps these operations but does not require every nonzero element to have a multiplicative inverse. Polynomial rings,

matrices, functions, modular arithmetic, and coordinate rings are all examples. The theory developed from algebraic number theory, algebraic geometry, invariant theory, and attempts to generalize complex numbers [1].

Hamilton's quaternions and other hypercomplex systems led mathematicians to matrix and noncommutative examples. Joseph Wedderburn identified finite-dimensional algebras with matrix structures, and Emil Artin generalized this work to Artinian rings. Emmy Noether's work on ideals and ascending chain conditions led to the term Noetherian ring and transformed modern algebra [2].

3. Theory

Core theory

313. Rings, ideals, and quotients.

A ring R has an abelian group structure under addition and an associative multiplication distributing over addition. It may have a multiplicative identity. A commutative ring satisfies $ab = ba$; a noncommutative ring need not.

An ideal I is an additive subgroup absorbing multiplication: ri and ir belong to I whenever $i \in I$ and $r \in R$. Ideals allow a quotient ring R/I , in which elements differing by something in I are identified. A ring homomorphism has a kernel that is an ideal, and the first isomorphism theorem says the image is isomorphic to the quotient by that kernel [1].

Prime and maximal ideals generalize prime numbers and fields. In a commutative ring, a prime ideal P satisfies $ab \in P$ only when $a \in P$ or $b \in P$. A maximal ideal has a field as quotient. These notions are the algebraic basis of the spectrum of a ring in algebraic geometry.

314. Modules and important classes.

A module over R is like a vector space in which scalars come from a ring instead of a field. Modules are the natural language for representations of rings and for systems of linear equations over the

integers. A ring is Noetherian when every ascending chain of ideals stops, or equivalently when every ideal is finitely generated.

An integral domain is a commutative ring without zero divisors. A field is a domain in which every nonzero element is invertible. A principal ideal domain has every ideal generated by one element, while a Euclidean domain has a division algorithm. The integers form a Euclidean domain; polynomial rings over fields often do as well.

Noncommutative rings include square matrix rings, endomorphism rings, group rings, and universal enveloping algebras. Their modules can be more complicated because left and right ideals differ. Morita theory studies when two rings have equivalent module categories, showing that the category of modules can be more important than the ring's particular presentation [3].

315. Structure and applications.

The Artin–Wedderburn theorem describes semisimple rings as products of matrix rings over division rings. Wedderburn's little theorem says every finite division ring is commutative, so it is a field. Nakayama's lemma controls generators of finitely generated modules over local rings. These results let algebraists replace a complicated ring by standard building blocks.

For an affine algebraic variety, regular functions form a coordinate ring. The geometry of the variety can be translated into ideal and quotient questions. The Hilbert Nullstellensatz connects maximal ideals of a polynomial ring over an algebraically closed field with points of the variety. Symmetric polynomials form an invariant ring; the fundamental theorem says they are generated by the elementary symmetric polynomials [4].

316. Application: Reed–Solomon codes.

A concrete connection between ring theory and coding theory arises through Reed–Solomon codes. Let $\mathbb{F}_q$ be a finite field with q elements, fix distinct elements $\alpha_1, \dots, \alpha_n \in \mathbb{F}_q$ with $n \leq q - 1$, and choose an integer $k \leq n$. The ring of polynomials $\mathbb{F}_q[x]$ provides the algebraic setting. A message is a polynomial $m(x) \in \mathbb{F}_q[x]$ of degree less than k . The encoder evaluates m at the fixed points, producing the codeword

$$c = (m(\alpha_1), m(\alpha_2), \dots, m(\alpha_n)).$$

The set of all such codewords forms a linear code of dimension k and length n . Two distinct degree- $(k-1)$ polynomials agree on at most $k-1$ points, so any two codewords differ in at least $n-k+1$ positions. This minimum distance guarantees that the code can correct up to $\lfloor (n-k)/2 \rfloor$ symbol errors.

The algebraic structure is essential: the set of codewords is an ideal in the ring $\mathbb{F}_q^n$ (under componentwise operations), and decoding can be performed by solving a system of polynomial congruences in $\mathbb{F}_q[x]$. Euclidean division in the polynomial ring provides the key algorithmic step. Reed–Solomon codes are used in QR codes, deep-space communication, and data storage systems such as CDs and DVDs [1].

4. Important theorems and results

- (a) **Ring isomorphism theorems.** Kernels, images, quotients, and induced maps obey analogues of the group isomorphism theorems.
- (b) **Nakayama’s lemma.** Over a local ring, generators of a finitely generated module can be detected after reducing modulo the maximal ideal.
- (c) **Artin–Wedderburn theorem.** A semisimple Artinian ring is a finite product of full matrix rings over division rings.
- (d) **Wedderburn’s little theorem.** Every finite division ring is a field.
- (e) **Hilbert basis theorem.** If R is Noetherian, then the polynomial ring $R[x]$ is Noetherian.
- (f) **Hilbert Nullstellensatz.** Over an algebraically closed field, maximal ideals of a polynomial ring correspond to points, and ideals describe the polynomial equations vanishing on sets.

Source for these results: [1].

5. Applications

Addition, multiplication, ideals, and modules describe algebraic systems in which factorization and quotient structure can be studied

together.

- (a) Algebraic geometry
- (b) algebraic number theory
- (c) coding theory
- (d) invariant theory
- (e) noncommutative geometry
- (f) linear algebra
- (g) and homological algebra.

6. Connections

Using existing theories

- (a) Groups describe addition and multiplication separately, while ring theory studies when these operations interact through distributivity.
- (b) Modules generalize vector spaces when coefficients come from a ring rather than a field, and ideals identify which expressions should count as zero in a quotient.
- (c) Polynomial rings turn equations into ring elements, so factoring, divisibility, and quotienting become tools for studying geometric solution sets [1, 2].

Helping other theories

- (a) Ring theory helps algebraic geometry by translating a variety into its coordinate ring, where geometric inclusion becomes ideal inclusion.
- (b) In number theory, ideals restore a workable factorization theory in rings where elements do not factor uniquely.
- (c) Modules support representations and homological algebra, while quotient rings over finite fields provide the arithmetic used to construct and decode error-correcting codes [1, 3].

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1. Find the ideals of $\mathbb{Z}$.** Every ideal is $n\mathbb{Z}$ for a unique nonnegative integer n . If an ideal contains a least positive element n , division with remainder shows every element is a multiple of n .
- (b) **Exercise 2. Describe $\mathbb{Z}/6\mathbb{Z}$.** Its elements are the six residue classes. The class of 2 is a zero divisor because $2 \cdot 3 = 0$ modulo 6, so the quotient is not a field.
- (c) **Exercise 3. Why is $2\mathbb{Z}$ an ideal of $\mathbb{Z}$?** It is closed under addition and negatives, and multiplying an even number by any integer remains even.
- (d) **Exercise 4. Is $\mathbb{Z}/5\mathbb{Z}$ a field?** Yes. Every nonzero class has an inverse because 5 is prime; for example $2^{-1} = 3$ since $2 \cdot 3 = 6 \equiv 1$ modulo 5.
- (e) **Exercise 5. Why are matrices a noncommutative ring?** Matrix addition and multiplication satisfy the ring laws, but usually $AB \neq BA$. The failure of commutativity is exactly why left and right ideals and modules must be distinguished.

Chapter 70

Scheme theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How can algebraic geometry describe equations over arbitrary rings, remember multiplicities, and retain information lost when a field has too few visible points?

Formal

A scheme is a space built from commutative rings. An affine scheme is the spectrum of a ring, whose points are prime ideals; a general scheme is obtained by gluing affine pieces together with a sheaf of functions. Schemes generalize varieties and unite geometry, topology, commutative algebra, and number theory.

2. History

Historical development

(a) **Alexander Grothendieck.**

Grothendieck introduced schemes in the 1960s to unify algebraic geometry over arbitrary rings. By using prime spectra

and sheaves, he made nilpotents, generic points, and families part of the geometric object rather than information discarded by its visible points.

(b) **Pierre Deligne and arithmetic geometers.**

Deligne used scheme-theoretic and cohomological methods to prove the remaining Weil conjecture. This demonstrated that schemes are not only a general language for varieties but also a working framework for arithmetic geometry [1, 3].

3. Theory

Core theory

317. Why varieties are not enough.

An algebraic variety is the set of solutions to polynomial equations, often over the complex numbers. This picture loses information over smaller fields. The equation $x^2 + y^2 = -1$ has no real points but has complex points. A scheme over the real numbers remembers how the equations behave over every field extension, not only what is visible in the real plane [1].

Schemes also remember multiplicity. The equations $x = 0$ and $x^2 = 0$ have the same visible solution set, but the second has a doubled structure. That extra information matters when studying intersections, tangent directions, and families in which components merge [2].

318. Alexander Grothendieck and the spectrum.

Alexander Grothendieck introduced schemes in the 1960s in *Elements of Algebraic Geometry*. He wanted a flexible language for algebraic geometry over arbitrary bases, including the integers, and for deep problems such as the Weil conjectures. Pierre Deligne later proved the last Weil conjecture using this framework [1, 3].

For a commutative ring R , the affine scheme $\text{Spec}(R)$ is the set of prime ideals of R . It has the Zariski topology, in which closed sets are

$$V(I) = \{\mathfrak{p} : I \subseteq \mathfrak{p}\}.$$

Maximal ideals behave like ordinary points, while non-maximal prime ideals are generic points of irreducible subspaces. The structure sheaf assigns a ring of regular functions to each open set. On a basic open set where f is nonzero, the functions are obtained by allowing powers of f in denominators [2].

319. Concrete illustration: $\text{Spec}(\mathbb{Z})$ and $\text{Spec}(k[x])$.

$\text{Spec}(\mathbb{Z})$ has one point for each prime (p) and a generic point (0) . The closure of (0) is the whole space, reflecting that every nonzero integer is divisible by some prime. The basic open set $D(n) = \{(p) : p \nmid n\}$ is the set of primes not dividing n ; the ring of functions on $D(n)$ is $\mathbb{Z}[1/n]$, the integers with n inverted. For example, $D(6)$ consists of all primes other than 2 and 3, and its function ring is $\mathbb{Z}[\frac{1}{6}]$. This space encodes the arithmetic of $\mathbb{Z}$: a closed subset $V(p_1 \cdots p_k)$ is a finite set of primes, while the generic point sits in every nonempty open set.

$\text{Spec}(k[x])$ over a field k is the affine line. Its maximal ideals are $(x - a)$ for $a \in k$, so if k is algebraically closed these are exactly the k -points of the line. The zero ideal (0) is the generic point. The open set $D(x) = \{p : x \notin p\}$ removes only the origin; its function ring is $k[x, x^{-1}]$, the Laurent polynomials. The scheme remembers the origin as a point even though a generic rational function on the line is defined away from it. Comparing the two spectra: $\text{Spec}(\mathbb{Z})$ is a one-dimensional Noetherian space whose closed points are primes, while $\text{Spec}(k[x])$ is geometrically a line; both illustrate how a ring completely determines its spectrum [1, 2].

320. Gluing affine pieces.

A scheme is a locally ringed space covered by affine schemes. The rings on overlapping pieces must agree through localization maps. This is analogous to describing the surface of a sphere with several maps: no single coordinate chart covers the whole surface, but compatible charts define the object.

The coordinate ring of $\text{Spec}(R)$ is R itself. A ring map $B \rightarrow A$ induces a scheme map $\text{Spec}(A) \rightarrow \text{Spec}(B)$ in the opposite direction. This contravariance is essential: functions pull back along geometric maps [1].

321. Morphisms, base change, and families.

The relative viewpoint studies a morphism $X \rightarrow S$ rather than an isolated scheme. A scheme over a ring R is a morphism $X \rightarrow \operatorname{Spec}(R)$. Base change replaces R by another ring and asks how the family changes. This lets one study the same equations over the integers, a finite field, the real numbers, and the complex numbers.

Moduli spaces classify geometric objects such as curves, vector bundles, or elliptic curves. A family of objects can itself have geometric structure, and schemes are designed to represent the functor that records all families. When objects have automorphisms, stacks extend schemes and algebraic spaces by remembering the symmetry groups [4].

322. Arithmetic and geometry.

The spectrum of the integers contains a generic point together with one point for each prime number. Thus arithmetic is represented as geometry. A scheme over the integers can be viewed as a family whose fibers over primes are reductions modulo p , while the generic fiber describes characteristic zero. This viewpoint links congruences, prime numbers, and geometric families.

The language of schemes underlies modern proofs in arithmetic geometry. Wiles's proof of Fermat's Last Theorem used modular forms, elliptic curves, and deformation theory in a setting naturally expressed through rings and schemes. The point is not that a scheme is a picture in space; it is a controlled system of local functions that preserves algebraic information [3].

4. Important theorems and results

- (a) **Affine correspondence.** Commutative rings and affine schemes are contravariantly equivalent: ring maps $B \rightarrow A$ correspond to morphisms $\operatorname{Spec}(A) \rightarrow \operatorname{Spec}(B)$.
- (b) **Hilbert Nullstellensatz.** For polynomial rings over algebraically closed fields, maximal ideals correspond to geometric points.
- (c) **Sheaf gluing principle.** Compatible affine pieces and their transition maps determine a scheme.
- (d) **Base-change principle.** A morphism can be pulled back

along another morphism, producing the corresponding geometric family over a new base.

- (e) **Grothendieck's cohomological framework.** Scheme cohomology turns local function data into global invariants and supports duality, intersection theory, and the Weil conjectures.
- (f) **Artin representability.** Under suitable conditions, a functor of families is represented by an algebraic space, and stack theory extends this to objects with automorphisms.

Source for these results: [1].

5. Applications

Prime spectra, localization, and sheaves preserve algebraic, infinitesimal, and arithmetic information in a geometric form.

- (a) Algebraic geometry
- (b) arithmetic geometry
- (c) moduli spaces
- (d) number theory
- (e) the Weil conjectures
- (f) and Fermat's Last Theorem.

6. Connections

Using existing theories

- (a) Commutative algebra supplies rings and ideals, and localization zooms in by allowing selected elements to become invertible.
- (b) The prime ideals form a space whose open sets reflect algebraic information, while a sheaf attaches the functions available on each open set.
- (c) This local-to-global construction lets a scheme remember nilpotent or arithmetic information that ordinary point sets would discard; homological algebra measures whether local data glue consistently [1, 2].

Helping other theories

- (a) Schemes help arithmetic geometry treat a ring of integers and a polynomial curve in one language, so statements can be compared across different primes and over the complex numbers.
- (b) They provide the base spaces for moduli problems, and their sheaves support intersection and deformation calculations.
- (c) In number theory, reduction modulo a prime becomes a fiber of a morphism, making local behavior part of a global geometric object [1, 3].
- (d) **Coding theory.** A Reed–Solomon code of length n over $\mathbb{F}_q$ is the set of evaluations of polynomials of degree less than k at n distinct elements $\alpha_1, \dots, \alpha_n \in \mathbb{F}_q$. The scheme $\text{Spec}(\mathbb{F}_q[x])$ provides the natural setting: each evaluation point α_i corresponds to the maximal ideal $(x - \alpha_i)$, and a codeword is a section of the structure sheaf over the open set $D(\prod_{i=1}^n (x - \alpha_i))$ restricted to those closed points. The minimum distance of the code equals $n - k + 1$, derived geometrically from the fact that a nonzero polynomial of degree $< k$ can vanish at most $k - 1$ times—equivalently, its zero scheme in $\text{Spec}(\mathbb{F}_q[x])$ has at most $k - 1$ closed points [1, 2].
- (e) **Cryptography.** Elliptic-curve cryptography (ECC) studies the group of K -rational points of a curve $E: y^2 = x^3 + ax + b$ over a finite field $\mathbb{F}_q$. Scheme theory treats E as a scheme over $\text{Spec}(\mathbb{F}_q)$ and considers the family of fibers E_p over all primes p . The Hasse bound $|E(\mathbb{F}_q) - (q + 1)| \leq 2\sqrt{q}$ is proved using the zeta function of the scheme E , which encodes point counts over all extension fields. Deformation theory over $\text{Spec}(\mathbb{Z})$ —studying how E changes modulo p —is the basis of the CM method for constructing curves with prescribed group orders, directly feeding into secure key generation for protocols such as ECDSA [3, 4].

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1. What are the points of $\mathrm{Spec}(\mathbb{Z})$?** They are the prime ideals (0) and (p) for each prime integer p . The ideals (p) are closed points, while (0) is generic.
- (b) **Exercise 2. Why is $\mathrm{Spec}(A)$ contravariant?** A ring map $B \rightarrow A$ lets a prime ideal of A pull back to a prime ideal of B . Therefore the induced geometric map goes from $\mathrm{Spec}(A)$ to $\mathrm{Spec}(B)$.
- (c) **Exercise 3. Compare $x = 0$ and $x^2 = 0$.** Both have the same closed point, but $k[x]/(x^2)$ contains a nonzero nilpotent element x . The scheme remembers the doubled or infinitesimal structure.
- (d) **Exercise 4. What is $\mathrm{Spec}(k[x])$ over an algebraically closed field?** Its maximal ideals $(x - a)$ correspond to points a of the affine line. The zero ideal is a generic point whose closure is the whole line.
- (e) **Exercise 5. Why study schemes over $\mathbb{Z}$?** A scheme over $\mathbb{Z}$ packages one characteristic-zero object together with its reductions modulo every prime, allowing arithmetic information to be studied as a family of fibers.

Chapter 71

Semigroup theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. What algebraic structure remains when a composition operation is associative but elements need not have inverses?

Formal

A semigroup is a set with an associative internal operation. It captures processes that can be performed in sequence, even when a process cannot be undone. Semigroup theory studies ideals, Green's relations, representations, finite structure, and links with automata and operators.

2. History

Historical development

(a) **Alexander Sushkevich and David Rees.**

Sushkevich studied the structure of finite semigroups, while Rees described important completely simple semigroups

through matrix-like constructions. Their work showed how associative composition can be analyzed without assuming inverses.

(b) **James Alexander Green and automata theorists.**

Green introduced the relations that organize semigroup elements by the principal ideals they generate. Later work connected these relations with finite automata, transformation systems, and operator theory, where irreversible composition is the central example [1].

3. Theory

Core theory

323. Definition and examples.

A semigroup is a set S with a product satisfying

$$(ab)c = a(bc)$$

for all $a, b, c \in S$. No identity and no inverse are required. String concatenation is associative: grouping the joins differently does not change the final string. Functions under composition form a semigroup, as do square matrices under multiplication and positive integers under addition.

A monoid is a semigroup with an identity. A group is a monoid in which every element has an inverse. Thus semigroups generalize groups by allowing irreversible processes such as a reset button, a lossy computation, or a function that is not reversible [1].

324. History and structure.

The systematic study began in the early twentieth century. Anton Sushkevich studied finite simple semigroups; David Rees and James Green developed structural tools; Alfred Clifford and Gordon Preston published foundational monographs. Green's relations divide a semigroup according to the principal ideals generated by its elements [2].

An ideal is a subset absorbing multiplication from the relevant side. Minimal ideals describe the long-term core of a finite semigroup. In

a finite semigroup, repeated products eventually repeat, so powers of an element enter a periodic part. This finite behavior is useful when a process is applied repeatedly.

325. Representations and finite semigroups.

Cayley's theorem for semigroups represents every semigroup as a semigroup of transformations of a set. An element is therefore a function, and multiplication is composition. This generalizes the group representation by permutations, replacing reversible bijections with arbitrary maps.

Finite semigroups are closely related to finite automata. A word read by an automaton induces a transformation of its state set. Words with the same effect form a syntactic monoid, and algebraic properties of this monoid characterize language classes. Krohn–Rhodes theory decomposes finite semigroups into simpler group and aperiodic components, analogous in spirit to factoring [3].

326. Automata and formal languages.

The connection between semigroups and automata theory is precise and deep. A deterministic finite automaton (DFA) reads input symbols from a finite alphabet Σ and updates its state according to a transition function $\delta: Q \times \Sigma \rightarrow Q$. Each symbol $a \in \Sigma$ therefore defines a transformation $q \mapsto \delta(q, a)$ of the state set Q . Concatenating symbols corresponds to composing these transformations, so every word $w \in \Sigma^*$ acts on Q as a transformation. The set of all transformations obtained from words forms the transition semigroup of the automaton [3].

The syntactic monoid of a regular language $L \subseteq \Sigma^*$ is the quotient of the free monoid Σ^* by the two-sided congruence that identifies words having the same effect in every left and right context of L . A fundamental theorem states that a language is regular if and only if its syntactic monoid is finite. More refined algebraic conditions on the syntactic monoid characterize proper sub-classes: a language is star-free if and only if its syntactic monoid is aperiodic (has no nontrivial group subgroups), and a language is piecewise testable if and only if its syntactic monoid is $\mathcal{J}$ -trivial. Krohn–Rhodes theory then decomposes the transition semigroup of any DFA into group and aperiodic components, with each component recognizing a specific aspect of the language's structure. This

algebraic decomposition provides both a classification tool and a design principle for automata [2, 3].

327. Analysis and differential equations.

A one-parameter operator semigroup is a family $T(t)$ with $T(0) = I$ and $T(t+s) = T(t)T(s)$ for $t, s \geq 0$. It describes evolution forward in time. Unlike a group, negative time may not be possible. If A is the generator, formally $T(t) = e^{tA}$.

The heat equation is an example. Starting with a temperature distribution $u(0)$, the heat semigroup sends it to $u(t)$ for later times. Diffusion smooths irregularities and loses information, so reversing it is unstable. Semigroup methods make existence, uniqueness, and stability of evolution equations precise [4].

4. Important theorems and results

- (a) **Cayley representation theorem.** Every semigroup is isomorphic to a semigroup of transformations under composition.
- (b) **Green's relations.** The relations $\mathcal{L}, \mathcal{R}, \mathcal{H}, \mathcal{D}, \mathcal{J}$ organize elements by their principal left, right, and two-sided ideals.
- (c) **Krohn–Rhodes theorem.** Finite semigroups admit decompositions into group components and aperiodic components in a precise wreath-product sense.
- (d) **Syntactic monoid theorem.** A regular language has a finite syntactic monoid, and its algebra records the language's behavior under contexts.
- (e) **Hille–Yosida principle.** Suitable conditions on an operator characterize when it generates a strongly continuous semigroup.

Source for these results: [1].

328. Application: image processing through mathematical morphology.

Mathematical morphology, a framework for image analysis, provides a direct application of semigroup theory. In this setting an image is a function from a discrete grid to a set of intensity values, and

basic operations are defined by a structuring element B . Dilation of an image f by B is the operation

$$(f \oplus B)(x) = \max_{y \in B} f(x - y),$$

and erosion is

$$(f \ominus B)(x) = \min_{y \in B} f(x + y).$$

When the structuring element is fixed, successive dilations compose associatively:

$$(f \oplus B) \oplus C = f \oplus (B \oplus C),$$

so the set of all dilations by elements from a fixed collection forms a semigroup under composition. Because dilation is generally not invertible—information about the original image can be lost—the inverse operation does not exist, and the algebraic structure is genuinely a semigroup rather than a group. Composite operations such as opening (erosion followed by dilation) and closing (dilation followed by erosion) are elements of this semigroup. The algebraic axioms of associativity guarantee that multi-step morphological filtering pipelines can be analysed and simplified by rearranging the semigroup product, which is the basis for efficient hardware and software implementations in image processing [1, 2].

5. Applications

Associative multiplication without universal inverses models irreversible composition, transition systems, and transformation actions.

- (a) String processing
- (b) finite automata
- (c) Markov processes
- (d) partial differential equations
- (e) linear systems
- (f) and the algebra of irreversible computation.

6. Connections

Using existing theories

- (a) A semigroup keeps the associative composition law while allowing inverses to be absent, which is exactly what irreversible processes require.
- (b) Functions under composition form the basic example: applying one transition after another gives a new transition, but it may not be reversible.
- (c) Automata use finite transformation semigroups to record the effect of reading words, while probability and functional analysis use semigroups to describe repeated or continuous evolution [1, 2].

Helping other theories

- (a) In formal-language theory, the syntactic semigroup compresses all words that have the same effect on acceptance, turning an infinite language question into a finite algebraic one when possible.
- (b) In a Markov process, a transition semigroup records the distribution after each elapsed time.
- (c) For a PDE such as heat flow, an operator semigroup maps the initial temperature to its later temperature, so composition expresses the passage of time [1, 3].

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1. Why is string concatenation a semigroup?**
Concatenating three strings in either order of parentheses produces the same sequence of symbols, so associativity holds.

- (b) **Exercise 2. Are all functions from a set to itself a monoid?** Yes. Composition is associative and the identity function is the identity element. It is generally not a group because most functions are not invertible.
- (c) **Exercise 3. What is the identity in the matrix semigroup of all 2 by 2 matrices?** The identity matrix is an identity for multiplication, but the set is not a group because singular matrices have no inverse.
- (d) **Exercise 4. Why is a heat evolution naturally a semigroup rather than a group?** Heat moves forward and smooths information. A later temperature profile usually does not determine a stable earlier profile, so backward evolution is not available as a bounded inverse.
- (e) **Exercise 5. How does an automaton produce a semigroup?** Each input word acts on the finite state set by a transformation. Combining words concatenates their transformations, giving a semigroup under composition.

Chapter 72

Set theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How can mathematics describe collections, compare different sizes of infinity, and build numbers and structures from simple membership rules?

Formal

Set theory studies sets and membership. It provides a language and foundation for most mathematics, while also investigating infinite sizes, ordinals, axioms, paradoxes, descriptive hierarchies, large cardinals, and independence.

2. History

Historical development

(a) The idea and history.

A set is a collection of objects, and membership is written $x \in A$. The empty set has no members. From sets we build pairs, products, functions, relations, numbers, spaces, and

algebraic structures. Richard Dedekind and Georg Cantor initiated modern set theory in the 1870s; Cantor is commonly regarded as its founder [1].

Cantor compared sizes by one-to-one correspondences. The natural numbers and even numbers have the same cardinality because $n \mapsto 2n$ is a bijection. The real numbers are uncountable: no list can contain every real number. This discovery made infinity a mathematical object rather than merely an endless process [2].

3. Theory

Core theory

329. Operations and cardinality.

The power set $\mathcal{P}(A)$ contains every subset of A . Cantor's theorem says there is no bijection from A onto $\mathcal{P}(A)$; the power set is strictly larger. A diagonal argument constructs a subset missing from any proposed list.

Cardinal numbers measure size. Finite cardinals behave like ordinary counting numbers; $\aleph_0$ is the size of the natural numbers. Ordinals measure order type: ω is the first infinite ordinal, followed by $\omega + 1$, $\omega + 2$, and so on. Cardinal and ordinal arithmetic differ because order matters for ordinals [3].

330. Axioms and paradoxes.

Naive set formation leads to contradictions. Russell's paradox considers the collection of all sets that do not contain themselves. If it contains itself, it should not; if it does not, it should. Other paradoxes include Cantor's paradox and the Burali–Forti paradox.

Zermelo–Fraenkel set theory, usually ZF, avoids these contradictions through axioms such as extensionality, pairing, union, power set, infinity, separation, replacement, foundation, and choice when AC is included. The axiom of choice says that a family of nonempty sets has a choice function. It is equivalent over ZF to Zorn's lemma and the well-ordering theorem [1].

331. The set-theoretic universe.

The cumulative hierarchy builds sets in stages. Start with the empty set, take power sets and unions repeatedly, and at limit stages take unions of earlier stages. The resulting von Neumann universe is written V . Each set has a rank, measuring the stage at which it appears.

The constructible universe L is an inner model built using definable subsets. Forcing, introduced by Paul Cohen, constructs models in which selected statements differ in truth value. Cohen proved that the continuum hypothesis and the axiom of choice have independence phenomena relative to ZF and ZFC. Thus axioms can leave some questions undecided [4].

332. Areas of study and applications.

Descriptive set theory studies definable subsets of the real line and Polish spaces through the Borel and projective hierarchies. Effective descriptive set theory connects these classes with recursion theory. Large-cardinal theory studies strong forms of infinity and their consistency strength. Set theory also supplies the formal basis for graphs, manifolds, rings, vector spaces, relations, and databases.

Category theory offers a different foundation: it emphasizes objects and relationships rather than membership. Set theory and category theory inform one another, but they organize mathematics in different ways [5].

4. Important theorems and results

- (a) **Cantor's theorem.** For every set A , $|\mathcal{P}(A)| > |A|$.
- (b) **Cantor diagonal theorem.** The real numbers are uncountable.
- (c) **Well-ordering theorem.** Every set can be well ordered, assuming the axiom of choice.
- (d) **Zorn's lemma.** A nonempty poset in which every chain has an upper bound has a maximal element.
- (e) **Löwenheim–Skolem phenomena.** First-order theories with infinite models have models of many cardinalities, showing that formal descriptions do not determine one intended universe.

- (f) **Independence results.** Some statements, including the continuum hypothesis, cannot be decided by the standard axioms without additional assumptions, relative to consistency results.

Source for these results: [1].

5. Applications

Membership, union, power sets, and cardinality specify the foundations from which mathematical collections are constructed.

- (a) Foundations
- (b) analysis
- (c) algebra
- (d) topology
- (e) computer science
- (f) formal semantics
- (g) logic
- (h) and the study of infinity.

6. Connections

Using existing theories

- (a) Set theory supplies a common way to collect objects, form products, and define functions and relations.
- (b) Logic specifies which collections and constructions are allowed, while proof checks that an operation preserves the required membership rules.
- (c) For example, a function is a set of ordered pairs with exactly one output for each input; this definition lets algebra, analysis, and computer science use the same concept without relying on a picture [1, 2].

Helping other theories

- (a) Set theory helps algebra and analysis build numbers, spaces, sequences, and functions from explicit objects.
- (b) It lets probability define a sample space and measurable events, and lets computer science describe data types and infinite computations.
- (c) Category theory then studies the maps between these constructions, while foundational results identify which collections can be formed without contradiction [1, 3].

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1. Why do the natural numbers and even numbers have equal size?** The map $n \mapsto 2n$ is one-to-one and onto the even numbers, so the two infinite sets have the same cardinality.
- (b) **Exercise 2. Why is $\mathcal{P}(\{a, b\})$ larger than $\{a, b\}$?** The power set has four members: $\emptyset, \{a\}, \{b\}, \{a, b\}$. There are more subsets than original elements.
- (c) **Exercise 3. Give the diagonal idea for showing that binary sequences cannot be listed.** From a proposed list, create a sequence whose n th digit differs from the n th digit of the n th listed sequence. The new sequence differs from every listed one.
- (d) **Exercise 4. Compare an ordinal and a cardinal?** A cardinal measures how many objects there are. An ordinal measures the order in which objects occur. Two different ordered sets can have the same cardinal but different ordinal types.
- (e) **Exercise 5. Why was an axiomatic system needed?** Unrestricted language about all collections creates self-reference

paradoxes. Axioms restrict set formation so that ordinary mathematics can be developed without those contradictions.

Chapter 73

Shape theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How can we describe the global shape of spaces that are too wild for ordinary homotopy theory?

Formal

Shape theory approximates complicated compact spaces by simpler polyhedra and records the compatible information that survives the approximation.

2. History

Historical development

(a) **The problem and history.**

Ordinary homotopy theory is powerful for polyhedra and manifolds, but wild spaces can have bad local behavior. Shape theory was introduced by D. E. Christie in 1944 and developed by Karol Borsuk, who coined the name in 1968 [1].

3. Theory

Core theory

333. Approximation by polyhedra.

The method replaces a compact space by a system of simpler polyhedral approximations. Each approximation has homotopy groups and homology, and maps between approximations record how descriptions refine one another. The shape is the resulting pro-system rather than one isolated approximation.

For compact spaces dominated homotopically by finite polyhedra, shape theory and homotopy theory agree. For general compact spaces, shape is more stable because it ignores microscopic details that disappear under increasingly fine approximation [2].

334. Concrete illustration: the Hawaiian earring vs. a wedge of circles.

The Hawaiian earring H is the union of circles C_n of radius $1/n$ all meeting at a single point p . The infinite wedge $\bigvee_{n=1}^{\infty} S^1$ is the disjoint union of countably many circles identified at one point, given the topology that makes each circle an open-and-closed subset.

Ordinary homotopy. A loop in H can traverse infinitely many circles, producing a homotopy group $\pi_1(H)$ that is uncountable and not free. The wedge $\bigvee S^1$ has the free group on countably many generators as its π_1 . So the two spaces are not homotopy equivalent.

Shape-theoretic view. Approximate H by the finite sub-wedge $H_N = \bigcup_{n=1}^N C_n$. Each H_N is homotopy equivalent to $\bigvee_{n=1}^N S^1$, and the inclusions $H_N \hookrightarrow H_{N+1}$ are compatible. Shape theory studies this inverse system of finite wedges and records the transition maps. The wedge $\bigvee S^1$ has the same inverse system, so the two spaces have the same shape even though they are not homotopy equivalent. Shape detects the large-scale pattern—a shrinking sequence of loops—while ordinary homotopy sees unmanageable microscopic entanglement [1, 2].

335. The Warsaw circle.

The Warsaw circle is formed by closing a topologist's sine curve with an arc. Its ordinary homotopy groups can look trivial, as for

a point, yet its global arrangement is not point-like. Shape theory detects the large-scale organization that ordinary homotopy groups miss [1].

336. Uses and generalizations.

Shape methods are useful for inverse limits, attractors in dynamical systems, and compact spaces arising as limits of finite approximations. Strong shape theory refines the invariants when ordinary shape loses information. Generalizations have been developed for noncommutative geometry, including shape theory for operator algebras.

337. A small worked example.

Imagine a coastline measured with rulers of length 1 kilometre, then 100 metres, then 10 metres. At each scale we replace the measured coastline by a simpler graph and record which pieces connect. A single graph may lose a narrow inlet, but the whole sequence shows whether that inlet persists as the scale becomes finer. Shape theory studies this compatible sequence rather than trusting one drawing.

The same idea applies to a dynamical attractor. A computer simulation gives finite samples, not the exact limiting set. If graphs built from increasingly fine samples preserve the same large-scale loops and components, those features are candidates for shape information. This is why shape theory is useful for spaces that are too irregular for a smooth coordinate description [1, 2].

4. Important theorems and results

- (a) **Approximation principle.** A compact space can be represented by a directed system of polyhedral approximations.
- (b) **Homotopy agreement.** For compact spaces dominated by finite polyhedra, shape and homotopy types coincide.
- (c) **Shape invariance.** Shape ignores changes that vanish under arbitrarily fine approximations.
- (d) **Warsaw-circle phenomenon.** A space can have trivial ordinary homotopy groups while possessing nontrivial global shape.

Shape theory is designed for spaces that are too irregular for a single smooth or polyhedral description. Approximation produces manageable models, homotopy agreement explains when those models recover ordinary topology, and shape invariance identifies changes that disappear at finer scales. The Warsaw-circle example gives the reason for the subject: ordinary homotopy groups can miss global information in wild compact spaces.

Source for these results: [1].

5. Applications

Inverse systems of simpler spaces preserve stable large-scale information when ordinary homotopy cannot handle a wild space.

- (a) General topology
- (b) dynamical systems
- (c) inverse limits
- (d) and noncommutative geometry.

6. Connections

Using existing theories

- (a) Topology and homotopy compare spaces by continuous maps, but a very wild space may have no useful finite description.
- (b) Shape theory replaces it by an inverse system of simpler spaces, records how the approximations refine one another, and declares two spaces equivalent when their entire systems agree up to compatible maps.
- (c) Category theory is needed because the compatibility of all approximations is part of the object, not an afterthought [1, 2].

Helping other theories

- (a) Shape theory helps continuum theory and geometric topology distinguish spaces whose local behavior is too irregular for ordinary homotopy groups.
- (b) In dynamics, a complicated invariant set can be approximated by a sequence of finite graphs or polyhedra, allowing global loops and connectedness to be studied through the approximations.
- (c) The method is useful because it preserves stable large-scale information while deliberately ignoring microscopic detail [1, 2].
- (d) **Image analysis and digital topology.** A digitized image is a finite grid of pixels, hence a finite polyhedron, but the continuous scene it samples may contain thin filaments, fractal boundaries, or wild crossings. Shape-theoretic approximations built from increasingly fine pixel grids detect whether a dark region truly has a hole (a nontrivial loop) or merely looks hollow at one resolution. For example, a medical image of lung tissue can be approximated by voxel complexes at successively finer CT scan resolutions. A shape invariant that persists across resolutions—such as a nontrivial first Čech cohomology class—signals a genuine airway passage, while an artifact at one resolution will vanish in the inverse system. Digital topology software implements this by computing pro-homology groups over a filtered complex, directly applying the shape-theoretic principle that only stable information is trustworthy [1, 2].

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1. Why use many approximations instead of one?** A single approximation may lose information. A directed system records how all approximations relate as the scale becomes finer.

- (b) **Exercise 2. When does shape agree with homotopy theory?** It agrees for compact spaces homotopically dominated by finite polyhedra.
- (c) **Exercise 3. Why can a wild space have trivial homotopy groups but nontrivial shape?** Homotopy groups examine maps from individual spheres. Shape also records how the entire space is organized as a limit of approximations.
- (d) **Exercise 4. What is the role of an inverse limit?** It creates a complicated limiting space from simpler stages; shape theory studies the stable information visible at those stages.
- (e) **Exercise 5. Why is shape useful in dynamics?** An attractor may be a complicated limit set. Polyhedral approximations can reveal persistent global structure even when local geometry is irregular.

Chapter 74

Sheaf theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How can locally defined information be organized so that compatible local pieces glue into a global object?

Formal

A sheaf assigns data to open regions of a space, restricts data to smaller regions, and requires compatible local data to glue uniquely. Sheaves may contain sets, groups, rings, modules, or vector spaces.

2. History

Historical development

(a) The problem and history.

Continuous functions, differentiable functions, vector fields, and solutions of differential equations are naturally defined on open subsets. A restriction map sends data on a large region to data on a smaller one. A presheaf is such an assignment; a

sheaf adds the condition that compatible local data determine exactly one global datum [?].

The theory grew from cohomology and analytic continuation. Jean Leray introduced sheaf methods in work on fixed-point theorems and partial differential equations. Henri Cartan and Alexander Grothendieck developed sheaf cohomology and its algebraic applications. Grothendieck later generalized open covers to Grothendieck topologies [?].

3. Theory

Core theory

338. Definition through an example.

Let X be a topological space. For each open set U , let $\mathcal{F}(U)$ be the set of data on U . If $V \subseteq U$, restriction gives a map $\mathcal{F}(U) \rightarrow \mathcal{F}(V)$. The sheaf condition says that if U is covered by open sets U_i and sections $s_i \in \mathcal{F}(U_i)$ agree on overlaps $U_i \cap U_j$, then there is a unique section $s \in \mathcal{F}(U)$ restricting to every s_i .

The sheaf of continuous real-valued functions satisfies this rule: compatible continuous pieces define one continuous function. The sheaf of smooth functions, holomorphic functions, vector fields, and sections of a vector bundle provide richer examples. The constant presheaf may fail to be a sheaf because locally constant choices can behave differently on disconnected regions [?].

339. Worked example: the sheaf of continuous functions on $\mathbb{R}$.

Let $X = \mathbb{R}$ with its usual topology, and for each open $U \subseteq \mathbb{R}$ let $\mathcal{F}(U) = C(U, \mathbb{R})$ be the set of continuous real-valued functions on U . If $V \subseteq U$, the restriction map $\rho_{UV}: \mathcal{F}(U) \rightarrow \mathcal{F}(V)$ sends a function f on U to its restriction $f|_V$. Now take the open cover $U_1 = (-\infty, 1)$ and $U_2 = (0, \infty)$ of $\mathbb{R}$. Suppose $f_1 \in \mathcal{F}(U_1)$ and $f_2 \in \mathcal{F}(U_2)$ agree on the overlap $U_1 \cap U_2 = (0, 1)$, meaning $f_1(x) = f_2(x)$ for every $x \in (0, 1)$. Then there is a unique continuous function $f: \mathbb{R} \rightarrow \mathbb{R}$ whose restriction to U_1 is f_1 and whose restriction to U_2 is f_2 : define $f(x) = f_1(x)$ for $x \leq 1$ and $f(x) = f_2(x)$ for $x > 0$. Agreement on the overlap guarantees continuity at every point. This is precisely the sheaf gluing axiom in action. Failure of agreement would

obstruct gluing: for instance, $f_1(x) = 0$ on $(-\infty, 1)$ and $f_2(x) = 1$ on $(0, \infty)$ cannot glue because they conflict on $(0, 1)$.

340. Morphisms and functors.

A morphism of sheaves is a collection of maps commuting with restriction. Sheaves of a fixed type on a space form a category. A continuous map $f : X \rightarrow Y$ gives a direct image functor f_* , which records data on inverse images, and an inverse image functor f^{-1} , which transports local data in the other direction. These functors and their derived versions are central to geometry [?].

341. Cohomology and geometry.

Sheaf cohomology measures the failure of local data to glue globally. Degree zero records global sections. Higher cohomology detects obstructions such as a locally defined function or solution that cannot be chosen consistently over the whole space. It includes familiar topological cohomology and connects local analytic information with global invariants.

Manifolds and schemes can be described using sheaves of rings. Divisors, vector bundles, and differential operators are naturally sheaf-theoretic. D-modules use sheaves of differential operators to study linear differential equations. In algebraic geometry, coherent sheaves package algebraic families and support duality and Riemann–Roch theory [?].

342. Sites, topoi, and arithmetic.

The Zariski topology on an algebraic variety has very few open sets, so ordinary constant-sheaf cohomology cannot recover the desired information over finite fields. Grothendieck topologies replace open covers by abstract covering families. A category with such coverings is a site, and sheaves on it form a Grothendieck topos.

Etale and l-adic sheaf cohomology supplied the cohomological tools used in the proof of the Weil conjectures. Topoi also connect sheaves with mathematical logic, and sheaf constructions on categories provide flexible foundations for arithmetic geometry [?].

4. Important theorems and results

- (a) **Sheaf gluing axiom.** Compatible local sections on a cover glue uniquely to a global section.
- (b) **Sheafification.** Every presheaf admits a universal sheaf receiving a map from it.
- (c) **De Rham theorem.** On a smooth manifold, the cohomology of differential forms agrees with singular cohomology.
- (d) **Serre's coherent sheaf theory.** Coherent sheaves connect algebraic functions, vector bundles, and cohomology on projective varieties.
- (e) **Grothendieck duality.** Under suitable hypotheses, direct and inverse image operations are related by dualizing functors.
- (f) **Etale cohomology.** Sheaf cohomology for the etale topology provides arithmetic invariants unavailable from the Zariski topology alone.

Source for these results: [?].

5. Applications

Restriction maps and gluing turn compatible local data into global sections and measure the failure when gluing is impossible.

- (a) Topology
- (b) algebraic and differential geometry
- (c) algebraic geometry
- (d) differential equations
- (e) cohomology
- (f) logic
- (g) and number theory.

6. Connections

Using existing theories

- (a) Topology provides open sets and overlaps, while a sheaf assigns data to each open set together with restriction maps to smaller sets.
- (b) The gluing rule says that compatible local sections come from one and only one global section.
- (c) Algebra decides what the sections are, and homological algebra measures the failure of gluing when the compatibility equations have no global solution $[?, ?]$.

Helping other theories

- (a) Sheaf theory helps geometry describe functions, vector fields, and solutions of differential equations that are defined locally but may fail to fit globally.
- (b) On a scheme it records regular functions and modules; in arithmetic it organizes information over different localizations; in logic it models varying truth values.
- (c) Cohomology turns the failure of gluing into invariants, so a local calculation can reveal a global obstruction $[?, ?]$.

Data fusion and sensor networks. A sensor network deploys many sensors over a region, each producing local measurements (temperature, air quality, acoustic signals) on its own coverage area. A sheaf on the network's topology assigns to each open set of sensors the data they collectively observe, with restriction maps encoding how data from a larger group restricts to a subgroup. The sheaf condition requires that overlapping sensor groups produce consistent readings. When readings conflict on overlaps, sheaf cohomology in degree 1 measures the inconsistency. This is used in practice: Baryshnikov and Ghrist introduced sheaf-based methods for distributed sensing, and real-time data-fusion algorithms use sheaf Laplacians to detect and localize sensor faults. A sensor reporting erroneous data creates a nontrivial cocycle; optimizing the sheaf Laplacian's smallest nonzero eigenvalue pinpoints which sensor is the source of the inconsistency.

7. Sample Questions

Exercise reference: [?]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1. Why do continuous functions form a sheaf?** Compatible continuous functions on overlapping open sets agree where they meet, so defining the combined function piece by piece is well defined and continuous.
- (b) **Exercise 2. What does the sheaf condition add to a presheaf?** It guarantees existence and uniqueness of a global object from compatible local objects; restriction alone does not guarantee this.
- (c) **Exercise 3. What does degree-zero sheaf cohomology represent?** It is the group or set of global sections, because no gluing obstruction remains at degree zero.
- (d) **Exercise 4. Why are schemes described by sheaves of rings?** Polynomial coordinates and regular functions vary from one open region to another. A sheaf records those local rings and their compatibility.
- (e) **Exercise 5. Why introduce the étale topology?** The Zariski topology has too few opens over finite fields. Étale covers provide enough local information to build useful cohomology.

Chapter 75

Sieve theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How can we estimate the size of a set of integers after removing numbers divisible by selected primes?

Formal

Sieve theory develops weighted versions of the sieve of Eratosthenes. It estimates sifted sets, often primes or almost-primes, without testing every integer.

2. History

Historical development

(a) **The idea and history.**

To find primes up to X , cross out multiples of 2, then 3, then 5, and so on. This is the sieve of Eratosthenes. Viggo Brun introduced the word sieve in 1915 and adapted the idea to questions about prime pairs [1].

Let $\mathcal{A}$ be a sequence of nonnegative weights and $\mathcal{P}$ a set of primes. If $P(z)$ is the product of primes in $\mathcal{P}$ below z , a basic sifted sum is

$$S(\mathcal{A}, \mathcal{P}, z) = \sum_{\substack{n \\ (n, P(z))=1}} a_n.$$

It counts or weights members of $\mathcal{A}$ not divisible by selected small primes. Weights are useful because the exact prime indicator is hard to handle, while a smooth approximation can be estimated [2].

3. Theory

Core theory

343. Main sieves and the parity problem.

The Brun sieve, Selberg sieve, Turan sieve, large sieve, larger sieve, and Goldston–Pintz–Yildirim sieve use different weights and information about residue classes. A sieve often replaces primes by almost-primes, numbers with only a few prime factors, because almost-primes are easier to count.

The parity problem says that ordinary sieve information is poor at distinguishing integers with an odd number of prime factors from integers with an even number. This is why sieve methods alone have difficulty proving the twin prime conjecture, even when they can prove that numbers with two prime factors occur infinitely often [3].

344. Major results.

Brun’s theorem proves that the sum of reciprocals of twin-prime pairs converges. Chen’s theorem proves that infinitely many primes p have $p+2$ either prime or semiprime. Chen also proved that every sufficiently large even number is a prime plus a prime or semiprime.

The fundamental lemma estimates the number left after a controlled number of sifting steps. It is usually too weak to isolate all primes, but it is powerful for almost-prime results. The Friedlander–Iwaniec theorem proves infinitely many primes of the form $a^2 + b^4$. Zhang’s theorem proved infinitely many prime pairs within a bounded

distance, and Maynard–Tao methods gave stronger bounded-gap results [3, 4].

345. Applications and limits.

Sieve estimates combine with the circle method, distribution estimates, and analytic number theory. They count primes in polynomial sequences, control exceptional sets, and provide upper bounds for prime patterns. Factorization algorithms called the quadratic sieve and number-field sieve use related ideas but are distinct computational methods.

4. Important theorems and results

- (a) **Fundamental lemma.** Under suitable distribution hypotheses, a sifted set can be estimated after a controlled number of prime exclusions.
- (b) **Brun’s theorem.** The reciprocal sum over twin primes converges.
- (c) **Chen’s theorem.** Infinitely many primes have a companion two units away that is prime or semiprime.
- (d) **Friedlander–Iwaniec theorem.** Infinitely many primes are represented by $a^2 + b^4$.
- (e) **Zhang’s bounded-gap theorem.** Infinitely many pairs of primes occur within some fixed finite distance.
- (f) **Maynard–Tao theorem.** Bounded intervals contain arbitrarily many primes for infinitely many choices of the interval, with a bound depending on the desired number.

Source for these results: [1].

5. Applications

Inclusion-exclusion over prime divisors produces upper and lower bounds for arithmetic sets that are difficult to count directly.

- (a) Prime distribution

- (b) twin-prime questions
- (c) almost-primes
- (d) bounded gaps
- (e) and analytic number theory.

6. Connections

Using existing theories

- (a) Sieve theory starts with inclusion–exclusion: to count numbers with no forbidden prime divisor, subtract multiples of each prime, add back multiples of pairs, and so on.
- (b) Congruences describe which residue classes survive, divisor sums organize the repeated inclusion–exclusion, and analytic estimates control the error created when the calculation is truncated.
- (c) The art is to keep enough local information to get a useful global bound without needing to know every prime factor exactly [1, 2].

Helping other theories

- (a) A sieve can upper-bound how many integers represent a sum of primes or have a prescribed pattern of prime factors, even when proving primality itself is out of reach.
- (b) This supplies almost-prime results in additive number theory and bounds for prime gaps.
- (c) Its output is often an inequality rather than an exact count, because discarded correlations between divisibility conditions are precisely what make a simple sieve tractable [1, 3].

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1. What numbers remain after sieving 1 through 20 by primes 2 and 3?** Remove multiples of 2 or 3. The remaining numbers are 1, 5, 7, 11, 13, 17, 19.
- (b) **Exercise 2. Why does a sieve count almost-primes more easily than primes?** Divisibility by small primes can be controlled, but proving that no larger prime factor remains is harder. Allowing a bounded number of factors avoids the final test.
- (c) **Exercise 3. Why does the parity problem obstruct?** It obstructs reliably separating numbers with an odd number of prime factors from those with an even number.
- (d) **Exercise 4. Why are weights used?** Weighted sums can approximate a difficult prime indicator while interacting well with congruences and averaging.
- (e) **Exercise 5. What did Chen's theorem achieve?** It reached near versions of the twin-prime and Goldbach goals by replacing one required prime with a semiprime.

Chapter 76

Singularity theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How do spaces, maps, and physical patterns change when a smooth or regular situation degenerates?

Formal

Singularity theory studies points where manifold structure fails, critical points of maps, and sudden changes under parameter variation. It classifies stable local models and studies how singularities arise by projection, symmetry, or degeneration.

2. History

Historical development

(a) The idea and history.

A string is a one-dimensional manifold until it crosses itself. A crossing is a double point; a touching point can disappear after a tiny movement and is unstable. Singularity theory asks

which irregularities persist under small changes and which are artifacts of a special drawing [1].

Vladimir Arnold described the subject as the study of how objects depend on parameters when a small change causes a sudden qualitative change. Whitney studied stable singularities and critical points; Rene Thom developed catastrophe theory; Arnold connected the subject with symplectic geometry and mechanics [2].

3. Theory

Core theory

346. Algebraic and geometric examples.

The curve $y^2 = x^2 + x^3$ has a double point at the origin, while $y^2 = x^3$ has a cusp. A singular point of a variety is one where the local equations do not define a smooth manifold. The Jacobian matrix detects this: the rank is too small at a singular point.

Singularities also arise by projecting a smooth object into lower dimensions. Caustics, such as bright patterns at the bottom of a swimming pool, occur where many light rays focus. Symmetry can create orbifolds with corners or cone-like points. A smooth manifold can degenerate into a singular space as parameters change [3].

347. Stability, germs, and catastrophes.

To classify a local singularity, one studies a germ, the behavior near a point, up to changes of coordinates. Taylor expansions and jets record derivatives up to a chosen order. Group actions identify equivalent local forms.

Catastrophe theory studies stable critical-point changes in families of smooth functions. Fold, cusp, swallowtail, and butterfly are standard elementary models. The models do not claim that every natural event is one of these shapes; they describe local mechanisms by which equilibria appear, merge, or disappear [1].

348. Resolution and duality.

Hironaka's resolution-of-singularities theorem in characteristic zero says that singularities of algebraic varieties can be replaced by a

smooth variety through a controlled sequence of transformations. The operation is not simply erasing a bad point; it records the exceptional geometry introduced during the resolution.

Singular spaces may fail Poincare duality. Intersection cohomology restores a form of duality by using the stratification of the singular space. Perverse sheaves arise from this framework and connect singularity theory with homological algebra. Monodromy studies how solutions or covering spaces behave around singularities of differential equations [4].

4. Important theorems and results

- (a) **Jacobian criterion.** Under standard hypotheses, a point of an algebraic variety is smooth exactly when the Jacobian has the expected rank.
- (b) **Whitney stability theory.** Stable singularities are those whose qualitative form persists under small perturbations.
- (c) **Morse lemma.** Near a nondegenerate critical point, a smooth function is equivalent to a quadratic form.
- (d) **Hironaka resolution theorem.** Algebraic varieties over characteristic zero admit resolutions of singularities.
- (e) **Intersection-cohomology duality.** Intersection cohomology restores a Poincare-type duality for broad classes of singular spaces.
- (f) **Classification of elementary catastrophes.** Low-dimensional stable critical changes reduce locally to a short list of normal forms.

Source for these results: [1].

5. Applications

Jacobian rank, local normal forms, and equivalence under coordinate changes classify where smooth behavior breaks down.

- (a) Algebraic geometry

- (b) differential geometry
- (c) wave fronts
- (d) optics
- (e) mechanics
- (f) catastrophe theory
- (g) bifurcation theory
- (h) and intersection cohomology.

6. Connections

Using existing theories

- (a) Calculus identifies where a map loses rank or a surface ceases to be smooth.
- (b) Differential and algebraic geometry classify the local equations, topology tests whether the local type survives small changes, and Lie group actions remove coordinate choices that do not change the singularity.
- (c) Homological tools then measure how cycles, intersections, or vanishing pieces appear when the singular point is resolved or deformed [1, 2].

Helping other theories

- (a) Singularity theory supplies normal forms for catastrophe and bifurcation models, so a complicated equation can be replaced locally by a short list of stable patterns.
- (b) In optics, the singular set of a ray map produces caustics and wave fronts; in algebraic geometry, resolutions and intersection cohomology recover information hidden by a singular point.
- (c) The same classification therefore links visible folds and cusps with algebraic invariants [1, 3].

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1. Is the origin singular on $y^2 = x^3$?** Write $F(x, y) = y^2 - x^3$. The gradient is $(-3x^2, 2y)$, which vanishes at $(0, 0)$. Thus the Jacobian criterion identifies a singular point, the cusp.
- (b) **Exercise 2. Why is a crossing more stable than a tangency?** A crossing persists under small generic perturbations, while a tangency can be removed by lifting one branch. Stability concerns persistence under perturbation.
- (c) **Exercise 3. What is a caustic?** It is an envelope or focused set of rays produced by a projection or optical map. Several smooth rays meet there, creating a singular visible pattern.
- (d) **Exercise 4. Why does a singular space need intersection cohomology?** Ordinary cohomology may fail duality because local neighborhoods are not manifold-like. Intersection cohomology restricts chains near singular strata to recover a duality theory.
- (e) **Exercise 5. What does resolution of singularities do?** It replaces a singular variety by a smooth one together with a map back, while keeping track of the exceptional sets created in the process.

8. References

Chapter 77

Soliton theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How can a nonlinear wave remain localized, keep its shape, and pass through another wave without being destroyed?

Formal

A soliton is a self-reinforcing localized wave in which nonlinearity balances dispersion. It travels at constant speed, preserves its form, and after a collision reappears with only a phase shift.

2. History

Historical development

(a) **Discovery and definition.**

Giorgio Bidone described a solitary water wave in 1826, and John Scott Russell observed one in 1834. Boussinesq and Rayleigh developed early mathematics. In 1895 Korteweg and de Vries derived the KdV equation. Zabusky and Kruskal

coined soliton in 1965 after numerical experiments showed particle-like collisions [1].

The usual properties are permanence of form, localization, and elastic interaction. Some physical pulses called solitons lose energy or interact imperfectly, so the word is sometimes used more broadly [2].

3. Theory

Core theory

349. The balance of effects.

Dispersion makes different wavelengths travel at different speeds and tends to spread a pulse. Nonlinearity makes wave speed depend on amplitude and can steepen or focus it. A soliton occurs when these effects cancel. In an optical fiber, dispersion separates frequencies while the Kerr effect changes refractive index according to intensity.

The Korteweg–de Vries equation is

$$u_t + 6uu_x + u_{xxx} = 0.$$

It has traveling-wave solutions

$$u(x, t) = 2k^2 \operatorname{sech}^2(k(x - 4k^2t - x_0)).$$

Taller solitons travel faster.

350. Integrability and applications.

The Korteweg–de Vries equation, nonlinear Schrodinger equation, sine–Gordon equation, and modified KdV equation are integrable models. The inverse scattering transform converts a nonlinear evolution into a scattering problem whose data evolve simply. Lax pairs encode this structure and generate conserved quantities [3].

Two KdV solitons pass through one another and retain their shapes, but each experiences a phase shift. Undular bores contain trains of solitary waves in rivers. Internal ocean waves travel along density interfaces. Atmospheric solitons occur in temperature inversion layers. Optical solitons allow pulses to travel long distances in fiber communication without dispersive spreading.

Solitons also occur in plasmas, Josephson junctions, magnetic materials, and field theories. De Broglie's double-solution idea motivated nonlinear wave models in quantum mechanics, although this is not the standard formulation of quantum theory [2].

4. Important theorems and results

- (a) **KdV soliton solution.** The KdV equation has localized traveling waves whose height and speed are linked.
- (b) **Inverse scattering transform.** Integrable nonlinear equations can be solved from scattering data that evolve simply.
- (c) **Lax-pair principle.** A compatible pair of operators can encode an integrable evolution and generate conserved quantities.
- (d) **Elastic collision property.** Ideal solitons emerge with their shapes and speeds unchanged except for phase shifts.
- (e) **Nonlinear-Schrodinger solitons.** In optical fibers, nonlinear self-phase modulation can balance dispersion.

The common message is that special nonlinear waves can behave like stable particles. The KdV solution gives a concrete pulse, the Lax pair and inverse-scattering transform explain why an integrable equation can be solved, and the elastic-collision property identifies the distinctive soliton behavior. Optical solitons use the same balance between dispersion and nonlinearity, but real fibers add loss and perturbations, so the ideal theorem is an approximation to an engineering model.

Source for these results: [1].

5. Applications

A balance between dispersion and nonlinearity creates localized waves whose shape and collision behavior can be calculated.

- (a) Water waves
- (b) optical fibers
- (c) plasmas

- (d) atmospheric waves
- (e) condensates
- (f) and nonlinear optics.

6. Connections

Using existing theories

- (a) Nonlinear differential equations describe waves whose speed can depend on their height, so ordinary superposition no longer works.
- (b) Fourier and spectral analysis identify the modes, while geometry and inverse-scattering methods find special combinations whose dispersion and nonlinearity balance exactly.
- (c) That balance prevents a localized pulse from spreading as it travels; the pulse can collide with another one and re-emerge with its shape preserved, apart from a shift [1, 2].

Helping other theories

- (a) Soliton theory models pulses in optical fibers, shallow water, plasmas, and some condensed-matter systems.
- (b) In each case the useful connection is quantitative: the equation predicts a stable waveform, its speed, and how interactions change its position.
- (c) Integrable-system methods also provide exact test cases for numerical algorithms and reveal which features of a nonlinear PDE come from a hidden conserved quantity [1, 3].

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1. What two effects balance in a soliton?**
Dispersion spreads a wave; nonlinearity changes speed with amplitude. Their cancellation preserves the pulse.
- (b) **Exercise 2. What is the speed of the KdV pulse above?**
Its argument is $k(x - 4k^2t - x_0)$, so its speed is $4k^2$.
- (c) **Exercise 3. Why does a taller KdV soliton travel faster?** Its height is $2k^2$ while its speed is $4k^2$.
- (d) **Exercise 4. Why is the optical Kerr effect relevant?** It makes refractive index depend on intensity, producing nonlinear phase modulation that can cancel dispersive spreading.
- (e) **Exercise 5. Why is a soliton not just any localized wave?** It must also have persistent propagation and robust collision behavior in the ideal model.

Chapter 78

Spectral theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How can the eigenvalue and eigenvector ideas of matrices be extended to differential operators and infinite-dimensional spaces?

Formal

Spectral theory studies the spectrum of an operator, the values for which it lacks an inverse, and decomposes an operator into simpler modes. The spectrum may contain ordinary eigenvalues and continuous parts, so infinite-dimensional systems need more than a list of eigenvectors.

2. History

Historical development

- (a) The idea and history.

For a matrix, eigenvectors are directions that are only stretched, and eigenvalues are the stretching factors. David Hilbert developed an infinite-dimensional version while studying quadratic forms and infinitely many variables. Erhard Schmidt and Frigyes Riesz developed Hilbert-space foundations; von Neumann developed spectral theory for operators used in quantum mechanics [1].

The term spectrum was introduced in the mathematical setting before quantum mechanics connected it with atomic spectra. Hilbert was surprised that a theory developed from pure mathematical interest would explain physical energy levels [2].

3. Theory

Core theory

351. Spectrum and resolvent.

For an operator T , the spectrum $\sigma(T)$ is the set of complex numbers λ for which $T - \lambda I$ has no bounded inverse. Every eigenvalue belongs to the spectrum, but the spectrum can contain values that are not eigenvalues. The complement is the resolvent set, where the inverse exists and varies analytically with λ .

On a Hilbert space, self-adjoint operators have real spectrum. Their spectrum may contain discrete eigenvalues or a continuous part. The multiplication operator $(Tf)(x) = xf(x)$ on square-integrable functions has every point in an interval in its spectrum even though no nonzero function is concentrated at one point [3].

352. The spectral theorem.

The finite-dimensional spectral theorem says a Hermitian matrix is unitarily diagonalizable. In an infinite-dimensional Hilbert space, a self-adjoint or normal operator is represented by a spectral measure:

$$T = \int_{\sigma(T)} \lambda dE(\lambda).$$

Functions of T are defined by the same calculus, so expressions such as e^{tT} and square roots can be constructed from the spectrum.

For compact self-adjoint operators, the nonzero spectrum consists of eigenvalues with finite multiplicity that can accumulate only at

zero. Their eigenvectors form an orthonormal basis of the relevant closure. This generalizes principal-axis decomposition and explains why integral equations can be solved by modes [1].

353. Applications.

The vibration of a string, membrane, or drum becomes an eigenvalue problem for a differential operator. Frequencies are spectral values and eigenfunctions are normal modes. The question Can one hear the shape of a drum? asks how much geometric information is encoded by the spectrum.

In quantum mechanics, a self-adjoint operator represents an observable; its spectrum gives possible measurement values. In Fourier analysis, translation-invariant operators are diagonalized by frequency modes. In engineering, spectral radius and eigenvalues determine stability of discrete-time systems. Sturm–Liouville theory gives a powerful one-dimensional model for boundary-value problems [4].

4. Important theorems and results

- (a) **Spectral theorem.** Self-adjoint and normal operators on Hilbert spaces admit spectral-measure representations.
- (b) **Compact-operator theorem.** A compact self-adjoint operator has an orthonormal eigen-expansion with only possible accumulation at zero.
- (c) **Spectral mapping theorem.** For suitable functions f , the spectrum of $f(T)$ is $f(\sigma(T))$.
- (d) **Spectral-radius formula.** For a bounded operator, the spectral radius satisfies $r(T) = \lim_{n \rightarrow \infty} \|T^n\|^{1/n}$.
- (e) **Resolvent analyticity.** The inverse $(T - \lambda I)^{-1}$ is analytic on the resolvent set.
- (f) **Weyl's alternative.** For singular Sturm–Liouville endpoints, limit-point and limit-circle behavior determine the necessary boundary conditions.

Source for these results: [1].

5. Applications

Spectra and functional calculus decompose operators into modes that govern differential equations, vibrations, and quantum observables.

- (a) Differential equations
- (b) quantum mechanics
- (c) vibrations
- (d) Fourier analysis
- (e) integral equations
- (f) spectral geometry
- (g) and engineering.

6. Connections

Using existing theories

- (a) Linear algebra begins with eigenvalues of a matrix; spectral theory asks the same question for operators on spaces of functions.
- (b) Hilbert-space geometry supplies orthogonality and convergence, functional analysis controls unbounded operators, and complex analysis studies the resolvent where an inverse exists.
- (c) Differential equations enter because boundary conditions select the eigenfunctions that can be combined to represent a solution [1, 2].

Helping other theories

- (a) Spectral theory helps vibration analysis by decomposing a structure into normal modes, each with its own frequency.
- (b) It helps quantum mechanics because the spectrum of an observable gives possible measurement values, and it helps PDEs because expanding the initial data in eigenfunctions converts evolution into independent scalar equations.

- (c) In numerical analysis, computed eigenvalues reveal stability, resonance, and the dominant directions of a large system [1, 3].

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1. Find the spectrum of $A = \text{diag}(2, 5)$.** The matrix $A - \lambda I$ is invertible unless $\lambda = 2$ or 5 , so $\sigma(A) = \{2, 5\}$.
- (b) **Exercise 2. Why can a spectrum contain a non-eigenvalue?** An operator can fail to have a bounded inverse even when the equation $Tv = \lambda v$ has no nonzero solution. Continuous spectral behavior is the infinite-dimensional example.
- (c) **Exercise 3. What are the normal modes of a vibrating string?** They are eigenfunctions of the differential operator with the boundary conditions of the string. Each mode oscillates at its own spectral frequency.
- (d) **Exercise 4. Why is the spectrum of a self-adjoint operator real?** If $Tv = \lambda v$ for a nonzero vector, then $\langle Tv, v \rangle = \langle v, Tv \rangle$ forces $\lambda = \bar{\lambda}$. The full theorem extends this reality to continuous spectrum.
- (e) **Exercise 5. How does Fourier analysis diagonalize convolution?** Exponentials are eigenfunctions of translation and convolution. Each frequency is multiplied by the Fourier transform of the kernel, so the operator becomes multiplication in frequency space.

Chapter 79

String theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. Can the elementary particles be understood as different vibrations of one-dimensional objects, in a framework that also includes quantum gravity?

Formal

String theory replaces point particles by strings. Different vibrational states appear as different particles, and one closed-string state has the properties expected of a graviton. The framework uses quantum mechanics, relativity, extra dimensions, supersymmetry, branes, dualities, and conformal field theory.

2. History

Historical development

- (a) The problem and history.

General relativity describes gravity and spacetime on large scales, while quantum mechanics describes microscopic phenomena. Applying ordinary quantum rules to gravity produces serious difficulties. String theory began in the late 1960s as a model of the strong force, but its unwanted features suggested a quantum theory of gravity [1].

The early bosonic theory described only bosons. Superstring theories added supersymmetry, relating bosons and fermions. Five consistent ten-dimensional superstring theories were identified: type I, type IIA, type IIB, and two heterotic theories. In the 1990s, dualities suggested that they are limits of an eleven-dimensional framework called M-theory [2].

3. Theory

Core theory

354. Strings, worldsheets, and branes.

An open string is a segment; a closed string is a loop. As a string moves, it sweeps out a two-dimensional worldsheet. Quantizing its vibrational modes produces particle states. A massless closed-string mode has spin two and is interpreted as the graviton.

A brane is a higher-dimensional object on which open strings can end. D-branes carry charges and help describe gauge fields. Compactification hides extra dimensions by making them very small. The shape of compact dimensions determines particle masses, charges, and symmetries in the lower-dimensional theory [1].

355. Dualities and correspondence.

T-duality relates a string on a circle of radius R to one on a circle of radius proportional to $1/R$. Other dualities relate strong coupling to weak coupling and exchange different kinds of branes. These relations imply that apparently different theories are descriptions of one underlying structure.

The AdS/CFT correspondence, proposed in 1997, relates a gravitational string theory in an anti-de Sitter space to a conformal field theory on its boundary. It has been applied to black holes, nuclear matter, and strongly interacting condensed matter, although it is a

theoretical correspondence rather than an experimentally confirmed description of nature [3].

String theory has counted microscopic states of certain black holes and has produced mathematical tools in geometry, topology, and representation theory. Compactifications on Calabi–Yau spaces and other manifolds have been used to build models resembling particle physics. However, the theory has many possible vacua, lacks a complete nonperturbative definition in all settings, and has not yet made a uniquely verified prediction about our universe [4].

4. Important theorems and results

- (a) **Graviton mode.** Closed-string quantization contains a massless spin-two state interpreted as the graviton.
- (b) **Supersymmetry.** Superstring theories relate bosonic and fermionic states and improve consistency.
- (c) **Anomaly cancellation.** Consistency restricts the allowed dimensions and gauge groups of superstring theories.
- (d) **Duality principle.** Different perturbative string descriptions can represent the same physics.
- (e) **AdS/CFT correspondence.** A gravitational theory in a bulk spacetime can be related to a conformal field theory on its boundary.
- (f) **Black-hole microstates.** In special supersymmetric examples, string theory counts microscopic states reproducing the Bekenstein–Hawking entropy.

Source for these results: [1].

5. Applications

String vibrations, compactification, branes, and dualities connect particle states with quantum-gravitational geometry.

- (a) Quantum gravity
- (b) black holes

- (c) cosmology
- (d) nuclear and condensed-matter models
- (e) and pure mathematics.

6. Connections

Using existing theories

- (a) Quantum mechanics supplies superposition and probabilities, while general relativity supplies a dynamical geometry of space-time.
- (b) Replacing a point particle by a one-dimensional string changes the basic calculation from a particle path to a two-dimensional surface, whose consistency is governed by quantum field theory and conformal symmetry.
- (c) Extra dimensions, topology, and boundary conditions determine which vibrations are allowed and therefore which particle-like states appear [1, 2].

Helping other theories

- (a) String theory is useful in quantum gravity because the extended string softens some short-distance singularities and naturally includes a gravitational mode.
- (b) Its dualities relate apparently different physical descriptions, while branes and mirror symmetry have produced methods in geometry and topology.
- (c) Holographic models also connect a gravitational theory in one setting with a quantum field theory in another, giving concrete calculations for strongly interacting systems [1, 3, 5].

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1. Why can one string describe many particles?** A string has many vibrational modes. Each allowed mode has a different mass, spin, and charge, so the modes appear as different particles.
- (b) **Exercise 2. Why are extra dimensions needed?** Quantum consistency removes anomalies only in particular space-time dimensions. Compactifying the extra dimensions makes them unobservable at ordinary distances.
- (c) **Exercise 3. What is a D-brane?** It is a higher-dimensional object on which open-string endpoints can lie. Its excitations can produce gauge fields.
- (d) **Exercise 4. What does T-duality teach?** A large compact dimension and a small compact dimension can describe equivalent string physics, so size is not always an absolute observable.
- (e) **Exercise 5. Has string theory been experimentally established?** No. It is a mathematically rich candidate for quantum gravity, but no unique experimentally confirmed prediction has established it as the theory of nature.

Chapter 80

Sturm–Liouville theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How can a second-order differential equation reveal the natural modes and frequencies of a system?

Formal

Sturm–Liouville theory studies self-adjoint boundary-value problems, their eigenvalues, eigenfunctions, orthogonality, completeness, and oscillation. It turns differential equations into a spectral decomposition problem.

2. History

Historical development

- (a) **The problem and history.**

Jacques Sturm and Joseph Liouville developed the theory in the nineteenth century. A regular problem has the form

$$\frac{d}{dx} (p(x)y') + q(x)y = -\lambda w(x)y$$

on an interval, together with boundary conditions. The coefficient w is a positive weight. The goal is to find values of λ for which a nonzero solution exists and the corresponding eigenfunction [1].

3. Theory

Core theory

356. Eigenvalues and orthogonality.

For a regular problem, the eigenvalues are real, can be ordered

$$\lambda_1 < \lambda_2 < \cdots, \quad \lambda_n \rightarrow \infty,$$

and each has a unique eigenfunction up to multiplication by a constant. Eigenfunctions for different eigenvalues are orthogonal under

$$\langle f, g \rangle_w = \int_a^b f(x)g(x)w(x) dx.$$

After normalization they form an orthonormal basis, so suitable functions can be expanded as an eigenfunction series [2].

357. A model problem and its interpretation.

The equation $-y'' = \lambda y$ on $[0, \pi]$ with $y(0) = y(\pi) = 0$ has eigenfunctions $\sin(nx)$ and eigenvalues n^2 . A vibrating string is a sum of these normal modes. Separation of variables converts the heat, wave, and Laplace equations into Sturm–Liouville problems.

The one-dimensional time-independent Schrodinger equation is a Sturm–Liouville problem. Its eigenvalues are energy levels and eigenfunctions are stationary states. Bessel and Legendre equations can also be written in Sturm–Liouville form, explaining the orthogonality of special functions [3].

358. Singular problems and computation.

When an endpoint is infinite or a coefficient vanishes, the problem is singular. Weyl's limit-point and limit-circle alternative determines whether an additional boundary condition is needed. Numerical methods include shooting, finite differences, Rayleigh–Ritz, matrix variational methods, and spectral parameter power series.

4. Important theorems and results

- (a) **Reality and ordering.** Regular Sturm–Liouville eigenvalues are real, simple, and increase without bound.
- (b) **Orthogonality.** Eigenfunctions belonging to distinct eigenvalues are orthogonal with the weight w .
- (c) **Completeness.** Normalized eigenfunctions form an orthonormal basis of the weighted L^2 space.
- (d) **Oscillation theorem.** The n th eigenfunction has a controlled number of zeros in the interval.
- (e) **Rayleigh quotient principle.** The smallest eigenvalue minimizes an energy quotient among admissible nonzero functions.
- (f) **Weyl alternative.** Singular endpoints are classified as limit-point or limit-circle, determining boundary data.

Source for these results: [1].

5. Applications

Self-adjoint differential operators, boundary conditions, and weighted orthogonality produce discrete modes and eigenvalue expansions.

- (a) Vibrating strings and membranes
- (b) heat flow
- (c) quantum mechanics
- (d) Fourier series
- (e) acoustics

- (f) and numerical boundary-value problems.

6. Connections

Using existing theories

- (a) An ordinary differential equation with boundary conditions becomes a self-adjoint operator problem.
- (b) Integration supplies the weighted inner product, Hilbert spaces make orthogonality and convergence precise, and spectral theory proves that the allowed eigenvalues are the natural frequencies of the problem.
- (c) The boundary conditions are essential: they select which modes fit the physical domain and make the operator's spectrum discrete in the standard compact cases [1, 2].

Helping other theories

- (a) The eigenfunctions form a basis for expanding a temperature, displacement, or wave profile, so a PDE can be solved one mode at a time.
- (b) In quantum mechanics they are stationary states; in acoustics they are resonant shapes; in numerical analysis they provide basis functions whose eigenvalues reveal stiffness and stability.
- (c) The connection works because self-adjointness makes different modes orthogonal and keeps the expansion coefficients independently computable [1, 3].

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1.** Solve $-y'' = \lambda y$ with $y(0) = y(\pi) = 0$. For $\lambda = n^2 > 0$, $y = A \sin(nx) + B \cos(nx)$. The condition at zero

gives $B = 0$, and the condition at π gives $\sin(n\pi) = 0$, so $n = 1, 2, \dots$

- (b) **Exercise 2. Why are the sine functions orthogonal?** For different integers m, n , integration of $\sin(mx)\sin(nx)$ over $[0, \pi]$ gives zero.
- (c) **Exercise 3. What is the physical meaning of an eigenfunction of a string?** It is a normal mode that oscillates with one natural frequency without changing shape.
- (d) **Exercise 4. Why is a weight needed?** The self-adjoint operator defines its natural inner product through $w(x)$; orthogonality and normalization must use that physical density.
- (e) **Exercise 5. Why does separation of variables help a PDE?** It seeks products of one-variable functions. Each factor satisfies a Sturm–Liouville eigenproblem, and the full solution is assembled from the resulting modes.

Chapter 81

Surgery theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How can one construct or classify manifolds by cutting out a controlled part and replacing it with another part?

Formal

Surgery theory modifies a manifold along an embedded sphere, keeping track of the changes in homology, homotopy, and other invariants. In high dimensions it turns manifold classification into a sequence of obstruction problems.

2. History

Historical development

(a) **The operation and history.**

For an n -manifold, remove an embedded S^p with a tubular neighborhood $S^p \times D^q$ and glue in $D^{p+1} \times S^{q-1}$, where $n = p + q + 1$. The boundary is the same, so the replacement

produces another manifold. John Milnor called the method surgery; Andrew Wallace called it spherical modification [1]. Surgery arose from the classification of exotic spheres and became a central tool for manifolds of dimension greater than four. Morse theory shows that two manifolds are related by a sequence of such modifications exactly when they lie in the same cobordism class [2].

3. Theory

Core theory

359. What surgery controls.

The embedded sphere determines which homotopy class is changed. A surgery can kill a homotopy group, alter homology in a known degree, or simplify the fundamental group. The goal is to start with a manifold whose structure is known and produce one satisfying a desired property.

The main classification questions are whether a space with the homotopy type of a manifold is actually homeomorphic or diffeomorphic to one, and whether a homotopy equivalence between manifolds is homotopic to a diffeomorphism. For dimensions above four, surgery gives primary and secondary obstructions rather than a single complete invariant [3].

360. Worked example: surgery on S^3 .

Consider the three-sphere S^3 and perform surgery on an embedded circle $S^1 \subset S^3$. The normal bundle of S^1 in S^3 is trivial (since S^3 is parallelizable), so a tubular neighborhood looks like $S^1 \times D^2$. Surgery means removing this $S^1 \times D^2$ and gluing in $D^2 \times S^1$ along the common boundary $S^1 \times S^1$. The result is again S^3 : one can see this by observing that S^3 is the boundary of D^4 , and the surgery corresponds to attaching a 2-handle along the unknot, which does not change the manifold. More interestingly, surgery on a knotted $S^1 \subset S^3$ (a nontrivial knot) can produce exotic manifolds. For example, surgery on the right-hand trefoil knot with framing 1 yields the Poincaré homology sphere, a manifold with the same homology as S^3 but with $\pi_1 \cong$ the binary icosahedral group of

order 120. This shows that even in dimension three, surgery can change the topology in ways invisible to homology.

361. **Obstructions and the s-cobordism theorem.**

A normal map records a candidate manifold map together with stable normal bundle data. A primary obstruction in topological K -theory must vanish before a surgery obstruction can be defined. The secondary obstruction lies in an algebraic L -group. When it vanishes, surgery can produce the desired homotopy equivalence under suitable hypotheses.

The h-cobordism theorem says that an h-cobordism between simply connected manifolds of dimension at least five is a product. The s-cobordism theorem removes simple homotopy ambiguity and uses Whitehead torsion. These results explain why high-dimensional classification is tractable while dimensions three and four require different methods [4].

4. Important theorems and results

- (a) **Surgery construction.** Replacing $S^p \times D^q$ by $D^{p+1} \times S^{q-1}$ produces a controlled change of an n -manifold.
- (b) **Cobordism-surgery principle.** A cobordism can be decomposed into elementary surgeries.
- (c) **h-cobordism theorem.** A simply connected h-cobordism in dimension at least five is a product.
- (d) **s-cobordism theorem.** In the high-dimensional setting, vanishing Whitehead torsion characterizes when an h-cobordism is a product.
- (e) **Surgery exact sequence.** Manifold structures, normal invariants, and algebraic L -groups are linked by an exact sequence of classification problems.

Source for these results: [1].

5. Applications

Cutting out a tubular neighborhood and regluing it changes a manifold in a controlled way whose homotopy and obstruction data can be computed.

- (a) High-dimensional topology
- (b) cobordism
- (c) exotic spheres
- (d) manifold classification
- (e) and geometric topology.

6. Connections

Using existing theories

- (a) Surgery removes a tubular neighborhood of an embedded sphere in a manifold and replaces it with another piece having the same boundary.
- (b) Homotopy and homology calculate how this replacement changes the space, cobordism records the whole transformation, and vector bundles describe the normal data needed to perform it.
- (c) K-theory and L-theory turn the remaining geometric question into an algebraic obstruction, especially when a homotopy equivalence is to be improved to a genuine equivalence of manifolds [1, 2].

Helping other theories

- (a) Surgery theory classifies high-dimensional manifolds by reducing them to a sequence of controlled modifications.
- (b) It explains exotic spheres by showing when the standard sphere can be altered without changing its homotopy type, and it supplies the obstruction groups used in the h- and s-cobordism theorems.

- (c) The connection is powerful but dimension-sensitive: the Whitney trick and general-position arguments that make the algebra reliable are much weaker in low dimensions [3, 4].
- (d) **Three-manifold topology and the Poincaré conjecture.** Surgery theory was the conceptual engine behind the resolution of the Poincaré conjecture. Perelman's proof via Ricci flow can be viewed as a continuous, analytic version of surgery: as the flow progresses, singularities develop that are modeled on neck-pinch operations, and each singularity is resolved by a surgery that removes and replaces a cylindrical region. The classification program for three-manifolds—the Thurston geometrization conjecture, now a theorem—decomposes every closed 3-manifold along incompressible spheres and tori into pieces that each carry one of eight model geometries. Surgery-theoretic language (cutting along embedded spheres, tracking the effect on π_1 , and using obstruction theory) provides the combinatorial framework that organizes this decomposition and led to Perelman's proof.

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1. What is removed in a surgery?** A tubular neighborhood $S^p \times D^q$ of an embedded sphere is removed, and $D^{p+1} \times S^{q-1}$ is glued along the common boundary.
- (b) **Exercise 2. Why is the boundary preserved?** Both pieces have boundary $S^p \times S^{q-1}$, so the gluing matches the boundary data.
- (c) **Exercise 3. What can surgery do to homology?** It can add or remove a handle-like feature and therefore change homology in degrees related to p and $p + 1$. The exact change is computed from the attaching sphere.
- (d) **Exercise 4. What is the purpose of the primary obstruction?** It tests whether the stable vector-bundle data

needed for a normal map exists. Only after it vanishes is the secondary surgery obstruction defined.

- (e) **Exercise 5. Why is dimension important?** The Whitney trick and general-position arguments work much better in dimensions above four, enabling the h- and s-cobordism methods.

Chapter 82

Teichmuller theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How can we describe all complex structures that can be placed on the same topological surface?

Formal

Teichmuller theory studies marked Riemann surfaces, quasiconformal maps, moduli, and the geometry of the space of conformal structures. It separates a surface's topology from the choice of complex shape.

2. History

Historical development

(a) **The question and history.**

Bernhard Riemann observed that a closed surface of genus $g \geq 2$ requires $6g - 6$ real parameters, or $3g - 3$ complex

parameters, to describe its complex structures. Oswald Teichmüller introduced quasiconformal mappings and the space now named after him. Lars Ahlfors and Lipman Bers supplied major analytic foundations; William Thurston later developed a geometric compactification [1].

3. Theory

Core theory

362. Teichmüller space.

Fix a topological surface S . A point of Teichmüller space $\mathcal{T}(S)$ is a marked Riemann surface (X, f) , where $f : S \rightarrow X$ identifies the underlying topology. Two marked surfaces are equivalent when a conformal map between them respects the markings up to isotopy. The marking prevents different coordinate descriptions from being identified too early.

For genus $g \geq 2$, $\mathcal{T}(S)$ is a complex manifold homeomorphic to a ball of real dimension $6g - 6$. Forgetting the marking gives the moduli space of Riemann surfaces. The mapping class group acts on Teichmüller space, and the quotient is the moduli space, viewed as an orbifold because some surfaces have automorphisms [2].

363. Quasiconformal maps.

A quasiconformal map is allowed to stretch angles by a bounded amount. In local complex coordinates its dilatation is controlled by

$$\frac{|f_z| + |f_{\bar{z}}|}{|f_z| - |f_{\bar{z}}|} \leq K, \quad K \geq 1.$$

The case $K = 1$ is conformal. Teichmüller's theorem says that in each isotopy class between marked surfaces there is a unique map with minimum dilatation, the Teichmüller map [3].

364. Metrics and quadratic differentials.

The minimum dilatation defines the Teichmüller metric. Holomorphic quadratic differentials determine the directions in which the extremal map stretches and contracts. The Bers embedding realizes Teichmüller space as a bounded domain in a complex vector space of quadratic differentials.

Uniformization identifies hyperbolic Riemann surfaces with quotients of the upper half-plane by Fuchsian groups. Fenchel–Nielsen coordinates describe hyperbolic structures by lengths and twists. These coordinates make the moduli problem geometrically computable [4].

365. Applications.

Teichmuller theory helps classify surfaces, understand mapping class groups, study Kleinian and Fuchsian groups, and analyze dynamics of rational maps. It also appears in two-dimensional conformal field theory and string theory, where Riemann surfaces describe possible worldsheets.

4. Important theorems and results

- (a) **Teichmuller existence and uniqueness theorem.** Every isotopy class contains a unique quasiconformal map of least dilatation.
- (b) **Dimension theorem.** For genus $g \geq 2$, Teichmuller space has complex dimension $3g - 3$.
- (c) **Bers embedding.** Teichmuller space embeds as a bounded domain in a space of quadratic differentials.
- (d) **Uniformization theorem.** Simply connected Riemann surfaces are conformally equivalent to the disk, plane, or sphere.
- (e) **Mapping-class action.** The moduli space is the quotient of Teichmuller space by the mapping class group.

These results separate shape from topology. The existence and uniqueness theorem chooses the least-distorting map between marked surfaces; the dimension theorem counts the independent complex structures; and the Bers embedding gives a concrete analytic model. Forgetting the marking produces moduli space, where equivalent descriptions are identified and symmetries may create orbifold points.

Source for these results: [1].

5. Applications

Complex structures, quasiconformal maps, and quadratic differentials parameterize how a fixed surface can vary.

- (a) Complex analysis
- (b) hyperbolic geometry
- (c) mapping class groups
- (d) moduli spaces
- (e) geometric topology
- (f) dynamics
- (g) and string theory.

6. Connections

Using existing theories

- (a) Complex analysis describes charts on a Riemann surface, while quasiconformal maps measure how much a map stretches angles.
- (b) Hyperbolic geometry supplies a canonical metric for most surfaces, and topology fixes the genus and marking.
- (c) The extremal map between two marked surfaces gives a distance in Teichmuller space; quotienting by mapping-class actions forgets the marking and produces moduli space [1, 2].

Helping other theories

- (a) Teichmuller theory supplies a finite-dimensional space of complex structures, so geometric topology can study how a surface changes rather than one surface at a time.
- (b) Its geodesic and mapping-class dynamics describe iteration on moduli space, while conformal field theory and string theory use the same moduli to integrate over possible world-sheet geometries.

- (c) Quadratic differentials provide the concrete directions in which these deformations stretch [1, 5].

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1. How many real parameters describe a genus-3 surface?** The dimension is $6g - 6 = 18$ real parameters, or 9 complex parameters.
- (b) **Exercise 2. What does a marking do?** It identifies the varying Riemann surface with one fixed topological surface, so changes in complex structure can be compared without forgetting topology.
- (c) **Exercise 3. What does $K = 1$ mean?** The map has no angular distortion and is conformal.
- (d) **Exercise 4. Why is moduli space a quotient?** Teichmuller space remembers markings. Forgetting them identifies points related by a mapping class, producing the moduli space.
- (e) **Exercise 5. Why are quadratic differentials important?** They describe the horizontal and vertical stretching directions of extremal quasiconformal maps and provide coordinates for the complex structure of Teichmuller space.

Chapter 83

Theory of computation

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. Which problems can an algorithm solve, what resources does it need, and where are the limits of mechanical calculation?

Formal

The theory of computation studies formal models of computation and divides into automata and formal languages, computability, and complexity. It separates impossible problems from solvable ones and efficient algorithms from impractical ones.

2. History

Historical development

(a) **The question and history.**

Pioneers included Alonzo Church, Kurt Gödel, Alan Turing, Stephen Kleene, Emil Post, Rózsa Péter, John von Neumann,

and Claude Shannon. Turing machines, lambda calculus, recursive functions, register machines, and rewriting systems are different models with the same broad notion of effective calculation, supporting the Church–Turing thesis [1].

3. Theory

Core theory

366. Automata and languages.

Figure 83.1: Computation can be viewed as state transitions with increasing memory.

Finite automata recognize regular languages, such as strings matching a simple pattern. Pushdown automata recognize context-free languages, which describe nested syntax such as balanced parentheses. Linear-bounded machines recognize context-sensitive languages, and Turing machines recognize recursively enumerable languages. These form the Chomsky hierarchy [2].

367. Computability.

A set of natural numbers is decidable if a Turing machine halts and answers yes or no for every input. A function is computable if a machine halts with its value. The halting problem asks whether an arbitrary machine eventually stops on an input. Turing and Church proved that no algorithm decides this for all machines.

Rice’s theorem says every nontrivial property of the partial function computed by a machine is undecidable. Matiyasevich’s theorem solved Hilbert’s tenth problem negatively: no algorithm decides whether an arbitrary Diophantine equation has an integer solution [3].

368. Complexity.

Complexity theory studies resources such as time and space as functions of input size. The class P contains problems solvable in polynomial time. NP contains problems whose proposed solutions can be checked in polynomial time. The P versus NP problem asks whether every efficiently checkable problem is efficiently solvable.

Big-O notation suppresses machine-dependent constants and compares growth. Searching an unsorted list takes $O(n)$ steps, while binary search on a sorted list takes $O(\log n)$. Complexity classes, reductions, randomized computation, approximation, and circuit complexity organize the limits of efficient algorithms [4].

4. Important theorems and results

- (a) **Church–Turing thesis.** All effectively calculable functions are captured by equivalent formal models such as Turing machines and lambda calculus.
- (b) **Halting theorem.** No Turing machine decides whether every machine halts on every input.
- (c) **Rice’s theorem.** Every nontrivial semantic property of partial computable functions is undecidable.
- (d) **Cook–Levin theorem.** Boolean satisfiability is NP-complete.
- (e) **Matiyasevich theorem.** Hilbert’s tenth problem has no algorithmic solution.
- (f) **Space and time hierarchies.** With more time or space, machines can solve strictly more problems in broad formal settings.

Source for these results: [1].

5. Applications

Machine models, reductions, and resource bounds distinguish what can be computed from what is undecidable or infeasible.

- (a) Programming languages

- (b) compiler design
- (c) algorithms
- (d) cryptography
- (e) verification
- (f) artificial intelligence
- (g) and the foundations of mathematics.

6. Connections

Using existing theories

- (a) Logic defines what a computation is allowed to mean, discrete mathematics describes finite strings and graphs, and automata give simple machines whose behavior can be proved.
- (b) Algorithms provide the procedures being measured, while proof and probability distinguish guaranteed termination from expected performance.
- (c) Reductions are the key mechanism: they translate one problem into another while preserving the answer, so a lower bound for the first problem transfers to the second [1, 4].

Helping other theories

- (a) The theory supports programming languages by defining syntax, semantics, and the limits of what programs can compute.
- (b) It supports cryptography through hardness assumptions, verification through formal properties of all executions, and complexity theory through time and space bounds.
- (c) Thus a practical program can be judged not only by whether it works on examples, but by whether its specification is decidable and its resources are bounded [1, 2].

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1. Why is balanced-parenthesis recognition not regular?** A finite automaton has only finitely many states and cannot remember an arbitrarily large nesting depth. A pushdown automaton uses a stack, which supplies the needed memory.
- (b) **Exercise 2. What is undecidable about the halting problem?** It is not merely difficult; no algorithm can always halt and correctly decide whether an arbitrary program halts on an arbitrary input.
- (c) **Exercise 3. Why is binary search logarithmic?** Each comparison halves the remaining sorted interval. After k comparisons at most $n/2^k$ entries remain, so k is about $\log_2 n$.
- (d) **Exercise 4. What does NP mean?** It means that a proposed solution can be checked in polynomial time. It does not mean that every problem in NP is known to be hard.
- (e) **Exercise 5. Why are reductions useful?** A reduction transforms instances of one problem into another. If a known hard problem reduces to a new problem, an efficient algorithm for the new problem would solve the hard one.

Chapter 84

Theory of equations

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. When can polynomial equations be solved exactly, and when is a formula using radicals impossible?

Formal

The classical theory of equations studies polynomial equations, their roots, formulas, and the algebraic structures that control solvability. Its central historical problem was solved by Galois theory, which replaced formulas with symmetry groups.

2. History

Historical development

(a) The historical problem.

For a polynomial equation, mathematicians first sought expressions for roots using addition, subtraction, multiplication, division, and radicals. Linear, quadratic, cubic, and quartic

equations received formulas in antiquity and the Renaissance. Scipione del Ferro and Tartaglia found cubic methods; Cardano published them, and Ferrari supplied the quartic solution. Bombelli explained the complex numbers appearing in cubic formulas [1].

The general quintic resisted radicals. Ruffini gave an incomplete impossibility argument, and Niels Abel proved in 1824 that a general fifth-degree equation cannot be solved by radicals. Évariste Galois then gave a criterion: the equation is solvable by radicals exactly when its Galois group is solvable [2].

3. Theory

Core theory

369. Roots and systems.

The fundamental theorem of algebra says every nonconstant complex polynomial has a complex root, counted with multiplicity. Vieta's formulas relate coefficients to symmetric sums and products of roots. The discriminant detects repeated roots: it is zero precisely when the polynomial and its derivative share a root.

Linear systems were solved in antiquity; Cramer gave a general determinant formula in the eighteenth century. Today Gaussian elimination is usually more efficient. Systems of polynomial equations lead to resultants, Grobner bases, and algebraic geometry. Integer solutions are studied as Diophantine equations in number theory [3].

370. A worked example.

For

$$x^2 - 5x + 6 = 0,$$

factoring gives $(x - 2)(x - 3) = 0$, so the roots are 2 and 3. Vieta's formulas explain the calculation without factoring: the roots must add to 5 and multiply to 6. The discriminant is

$$(-5)^2 - 4(1)(6) = 1,$$

which is positive, so the two real roots are distinct.

The same questions become harder for a cubic or quintic. A numerical algorithm may approximate the roots, but the theory of equations asks a different question: is there a finite expression using radicals at all? Galois theory answers that question by studying how the roots can be permuted while leaving the coefficients fixed. Thus the elementary quadratic example is a model of the larger subject: coefficients constrain roots, symmetry explains the constraint, and the discriminant detects a change in the root pattern [1, 2].

4. Important theorems and results

- (a) **Fundamental theorem of algebra.** Every nonconstant complex polynomial has a complex root and factors completely into linear factors.
- (b) **Abel–Ruffini theorem.** The general polynomial of degree five or greater is not solvable by radicals.
- (c) **Galois criterion.** A polynomial is solvable by radicals exactly when its Galois group is solvable.
- (d) **Vieta’s formulas.** Coefficients determine elementary symmetric functions of the roots.
- (e) **Discriminant criterion.** A polynomial has a repeated root exactly when its discriminant is zero.
- (f) **Bezout’s theorem.** Projective plane curves of degrees m and n meet in mn points counted with multiplicity under suitable hypotheses.

Source for these results: [1].

5. Applications

Roots, multiplicities, resultants, and Galois symmetries explain both exact solvability and the limits of formulas.

- (a) Algebra
- (b) number theory
- (c) algebraic geometry

- (d) numerical root finding
- (e) physics
- (f) and the study of polynomial systems.

6. Connections

Using existing theories

- (a) Algebra supplies operations on coefficients, complex numbers guarantee that a polynomial factors into linear factors after passing to a suitable field, and linear algebra handles systems and multiplicities.
- (b) Symmetry enters because permuting the roots can preserve every coefficient; the set of such permutations is the Galois group.
- (c) Polynomial geometry then interprets several equations as a shape whose intersections and singularities encode the solutions [1, 2].

Helping other theories

- (a) The theory feeds Galois theory by turning the question “can roots be written by radicals?” into a question about solvable groups.
- (b) It feeds algebraic geometry through varieties and elimination, number theory through integer and rational roots, and numerical analysis through algorithms that approximate roots when no useful formula exists.
- (c) In physics, characteristic equations determine allowed frequencies or energy levels, so root structure becomes a prediction about a system [2, 3].

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement

and numbering.

- (a) **Exercise 1. Solve $x^2 - 5x + 6 = 0$.** Factor as $(x - 2)(x - 3)$, so the roots are 2 and 3.
- (b) **Exercise 2. What is the discriminant of $x^2 + bx + c$?** It is $b^2 - 4c$. It is zero exactly when the quadratic has a repeated root.
- (c) **Exercise 3. What is the general quintic have no radical formula?** Its generic Galois group is the nonsolvable group S_5 . Galois's criterion therefore forbids a formula by radicals.
- (d) **Exercise 4. What does Vieta say for $x^2 - 5x + 6$?** The sum of roots is 5 and their product is 6, matching $2 + 3$ and $2 \cdot 3$.
- (e) **Exercise 5. Why are multiplicities counted in intersections?** A tangent intersection or cusp can contribute more contact than a transverse crossing. Multiplicity makes Bezout's count remain constant under deformation.

Chapter 85

Theory of statistics

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How can limited, noisy observations support reliable conclusions about a much larger population or an uncertain process?

Formal

Statistical theory gives mathematical principles for study design, data collection, summarization, inference, prediction, and decisions. It connects probability with optimization and utility so that methods can be compared and their uncertainty quantified.

2. History

Historical development

(a) **Ronald Fisher.**

Fisher developed likelihood-based estimation, analysis of variance, and principles for randomized experimental design. These methods connected data collection with efficient

estimation and made experimental uncertainty part of the mathematical model.

(b) **Jerzy Neyman and Egon Pearson.**

Neyman and Pearson formalized hypothesis testing through error probabilities and power. Their framework distinguishes the rule used to make a decision from the long-run error guarantees attached to that rule [1, 2].

3. Theory

Core theory

371. The problem and scope.

Data are observations from a population or process, often with measurement error and random variation. A statistical model describes how the data could have been generated. Statistical theory asks which questions can be answered, how much information is needed, and how reliable an answer is [1].

Its tasks include sampling from finite populations, measuring error, describing distributions, estimating parameters, testing hypotheses, predicting outcomes, comparing groups, and reducing dimension. It also studies what happens when assumptions such as independence or a chosen distribution are wrong [2].

372. Design before analysis.

Randomization makes treatment groups comparable and supports probability statements. Experimental design chooses factors, controls, replication, and sample size to estimate treatment effects efficiently. Survey sampling chooses a representative sample while accounting for unequal selection probabilities and nonresponse.

Good design can reduce cost and uncertainty before any formula is applied. Observational studies can estimate associations but usually require stronger assumptions to infer causation. Statistical theory separates the information supplied by the design from conclusions added by a model [3].

373. Inference.

An estimator is a rule that turns data into a parameter estimate. Bias, variance, consistency, and efficiency compare estimators. A confidence interval gives a procedure that covers the true parameter at a stated long-run rate; it is not a probability statement about a fixed parameter after the interval is observed.

Hypothesis testing compares a null model with alternatives. A p-value measures how surprising data would be under the null, while power measures the chance of detecting a specified alternative. Bayesian inference combines a prior distribution with a likelihood to produce a posterior distribution. Decision theory chooses actions by expected loss or utility [4].

374. Models and robustness.

Regression models describe relationships and prediction. Dimension reduction replaces many variables by a smaller informative representation. Model checking examines residuals, dependence, outliers, and calibration. Robust methods reduce sensitivity to incorrect distributional assumptions.

4. Important theorems and results

- (a) **Law of large numbers.** Sample averages approach population means under suitable conditions.
- (b) **Central limit theorem.** Properly standardized sums often approach a normal distribution, explaining many large-sample intervals.
- (c) **Neyman–Pearson lemma.** For testing two simple hypotheses at a fixed error level, the likelihood-ratio test is most powerful.
- (d) **Gauss–Markov theorem.** In a linear model with standard assumptions, least squares is the best linear unbiased estimator.
- (e) **Sufficiency principle.** A sufficient statistic retains all information about a parameter contained in the sample under the model.
- (f) **Bayes theorem.** Posterior odds equal prior odds multiplied by the likelihood ratio.

Source for these results: [1].

5. Applications

Sampling distributions, estimators, likelihoods, and error control turn data into quantified conclusions about a population.

- (a) Experiments
- (b) surveys
- (c) medicine
- (d) engineering
- (e) economics
- (f) machine learning
- (g) public policy
- (h) and scientific data analysis.

6. Connections

Using existing theories

- (a) Probability describes the random mechanism that could produce the data, and statistics reverses that direction to infer unknown features of the mechanism.
- (b) Linear algebra makes regression and covariance computable, calculus derives likelihood equations, and optimization chooses parameters that fit the observations.
- (c) Decision theory adds the loss of acting on an estimate, so a statistically good answer is judged by consequences as well as by closeness to the data [1, 4].

Helping other theories

- (a) Statistical theory helps an experiment separate a real effect from sampling noise by comparing an estimate with its expected variability.
- (b) In medicine it turns trial data into risk estimates, in engineering it monitors failure rates, and in machine learning it controls prediction error on unseen data.

- (c) Surveys and public policy depend on the same connection, but only when sampling, missing data, dependence, and the decision costs are modeled explicitly [3, 5].

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1. What is the standard error of the mean of n independent observations with variance σ^2 ?** The sample mean has variance σ^2/n , so its standard error is $\sigma/\sqrt{n}$.
- (b) **Exercise 2. Why does randomization help an experiment?** It makes treatment assignment independent of uncontrolled characteristics in expectation, allowing differences in outcomes to be attributed to treatment under the design.
- (c) **Exercise 3. Compare a confidence interval and a prediction interval?** A confidence interval estimates an unknown population quantity; a prediction interval also includes the random variation of a future observation and is therefore wider.
- (d) **Exercise 4. What does a p-value not mean?** It is not the probability that the null hypothesis is true. It is a probability of data as extreme as observed, calculated assuming the null.
- (e) **Exercise 5. Why can a large sample produce a statistically significant but unimportant result?** Standard errors shrink with sample size, so a tiny effect can be detected. Practical importance requires an effect-size and cost or benefit assessment.

Chapter 86

Topology

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. Which properties of a space survive stretching, bending, and twisting when there is no tearing or gluing?

Formal

Topology studies spaces through open sets, continuity, compactness, connectedness, dimension, holes, and invariants. It ignores exact distances while retaining how parts fit together.

2. History

Historical development

(a) The idea and history.

Topology grew from Euler's solution of the Seven Bridges of Königsberg problem and his polyhedron formula. Listing introduced the term topology; Cantor studied point sets; Fréchet,

Hausdorff, and Kuratowski developed metric and general topological spaces. Dennis Sullivan's work illustrates the continuing interaction of algebraic, geometric, and dynamical topology [1].

3. Theory

Core theory

375. Spaces and continuity.

A topology on a set X is a collection of open sets containing $\emptyset$ and X , closed under arbitrary unions and finite intersections. A topological space is a set with such a collection. A metric defines a topology through open balls, but many useful topologies have no preferred distance.

A function is continuous when inverse images of open sets are open. A homeomorphism is a continuous bijection with continuous inverse; it means two spaces have the same topological shape. A homotopy continuously deforms one map into another. Compactness says that every open cover has a finite subcover, and connectedness means the space cannot be split into two disjoint open pieces [2].

376. Examples and invariants.

Figure 86.1: Topology studies features that survive continuous deformation.

A circle and a square are homeomorphic, while a circle and two disjoint circles are not connected in the same way. A coffee cup and a torus have one hole each in the relevant sense. The Mobius strip has one side and one boundary component. Euler characteristic, fundamental group, homology, and cohomology turn shape into computable algebra.

General topology studies open sets and convergence. Algebraic topology studies invariants such as homology and homotopy groups. Differential topology studies smooth manifolds, transversality, and tangent spaces. Geometric topology studies knots, manifolds, and embeddings [3].

4. Important theorems and results

- (a) **Euler characteristic.** For a finite cell decomposition, $\chi = V - E + F$ is independent of the chosen decomposition.
- (b) **Intermediate value theorem.** A continuous real function taking values on both sides of a number takes that value somewhere between.
- (c) **Heine–Borel theorem.** A subset of Euclidean space is compact exactly when it is closed and bounded.
- (d) **Brouwer fixed-point theorem.** Every continuous map from a closed disk to itself has a fixed point.
- (e) **Jordan curve theorem.** A simple closed curve in the plane separates the plane into an inside and an outside.
- (f) **Classification of surfaces.** Connected compact surfaces are classified by orientability, genus, and boundary data.

Source for these results: [1].

5. Applications

Continuity, open sets, connectedness, and homotopy capture properties unchanged by bending or stretching without tearing.

- (a) Analysis
- (b) geometry
- (c) differential equations
- (d) data analysis
- (e) dynamical systems
- (f) physics

- (g) and the classification of manifolds.

6. Connections

Using existing theories

- (a) Sets and functions define open sets and continuous maps, while analysis explains convergence and compactness.
- (b) Geometry contributes spaces with coordinates, and algebra records features that survive continuous deformation.
- (c) The central mechanism is to discard measurements such as exact length while retaining relations such as connectedness or the existence of a loop; this makes a stretched rubber band and a circular one equivalent for the questions topology asks [1, 3].

Helping other theories

- (a) Topology helps manifold theory provide local coordinate neighborhoods, and algebraic topology converts holes and loops into groups and homology.
- (b) Dynamical systems use open sets and compactness to control long-term behavior, while functional analysis uses topological vector spaces to define convergence of functions.
- (c) In data analysis, a point cloud can be thickened into a shape and its persistent holes can be compared even when the measurements are noisy [1, 4].

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1. Why are a circle and a square topologically equivalent?** A continuous bijection can map the boundary of the square once around the circle, and its inverse is continuous.

- (b) **Exercise 2. Compute the Euler characteristic of a tetrahedron.** It has $V = 4$, $E = 6$, and $F = 4$, so $\chi = 4 - 6 + 4 = 2$, the value for a sphere.
- (c) **Exercise 3. Is the interval $[0, 1]$ connected?** Yes. If it were split into two nonempty separated open pieces, the order structure of the real line would be contradicted.
- (d) **Exercise 4. Why is a continuous image of a compact space compact?** An open cover of the image pulls back to an open cover of the domain; a finite subcover there maps to a finite subcover of the image.
- (e) **Exercise 5. What does the fundamental group measure?** It records loops based at a point up to continuous deformation and detects holes such as the central hole of a circle.

Chapter 87

Topos theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. Can one build a mathematical universe that behaves like sets, but whose notion of space, logic, and truth is adapted to a particular problem?

Formal

A topos is a category behaving like sheaves of sets on a space or site. Grothendieck topoi organize geometry and cohomology; elementary topoi provide an alternative foundation with internal logic that may be constructive rather than classical.

2. History

Historical development

(a) Origin and intuition.

Topos theory arose when Grothendieck combined sheaves with categorical operations in algebraic geometry. Its important application is étale cohomology, which helped prove the Weil

conjectures. Later Lawvere and Tierney emphasized topos as logical universes; Olivia Caramello developed bridge methods between theories and topos [1].

The category of sets is the familiar example. A topos has objects, maps, products, function objects, a terminal object, and a subobject classifier. It therefore supports much of ordinary mathematics internally, but its logic can differ from classical set theory.

3. Theory

Core theory

377. Grothendieck and elementary topos.

The category of sheaves of sets on a topological space is a Grothendieck topos. More generally, sheaves on a site form a topos, even when the covering objects are not ordinary open subsets. This lets algebraic geometers choose the topology best suited to the problem.

An elementary topos is defined by finite limits, exponentials, and a subobject classifier. It can interpret intuitionistic logic, so the law of excluded middle need not hold. A topos of G -sets is useful when a group symmetry should be built into every object [2].

378. Concrete illustration: G -sets for a simple group.

Let $G = \mathbb{Z}/2\mathbb{Z} = \{0, 1\}$ act on a set $X = \{a, b\}$ by swapping a and b : the non-identity element of G sends $a \mapsto b$ and $b \mapsto a$. A G -set is any set with such a G -action; a morphism of G -sets is a map $f: X \rightarrow Y$ satisfying $f(g \cdot x) = g \cdot f(x)$ for all $g \in G$, $x \in X$.

The category $\mathbf{Set}^G$ of all G -sets is a topos. Its terminal object is the one-element set with trivial G -action. Products are cartesian products with G acting componentwise: $(X \times Y)_g = (x, y) \mapsto (g \cdot x, g \cdot y)$. The subobject classifier is $\Omega = \{0, 1\}$ where G acts trivially on both elements: the characteristic map of the G -invariant subset $\{a\} \subset \{a, b\}$ sends both a and b to 1, reflecting that $\{a\}$ is not G -stable and so its “truth value” is the whole of Ω .

This tiny example shows the topos machinery in action: internal logic (truth values in Ω), subobject classification (invariant subsets),

and the failure of excluded middle, since the proposition “ $x = a$ ” has no definite truth value when G may swap the points [1, 2].

379. Logic and applications.

The internal language of a topos treats objects as types or sets and arrows as functions. A subobject is a predicate, and its classifier behaves like a truth-value object. In a Boolean topos the internal logic is classical; in a general topos it is intuitionistic. This makes topos useful for constructive mathematics and semantics of computation.

Topoi connect category theory with algebraic geometry, homotopy theory, type theory, and logic. Classifying topoi represent geometric theories, while higher topoi extend the idea to homotopy-coherent spaces [3].

4. Important theorems and results

- (a) **Topos sheaf theorem.** Sheaves on a site form a Grothendieck topos.
- (b) **Subobject classifier.** In a topos, subobjects of an object correspond to maps into a distinguished truth-value object.
- (c) **Exponential object.** Maps into an exponential B^A correspond naturally to maps from a product with A into B .
- (d) **Lawvere–Tierney topology.** Local notions of truth and sheafification inside a topos are described by suitable closure operators.
- (e) **Giraud principle.** Grothendieck topoi can be characterized abstractly by categorical exactness and generator conditions. These results explain a topos at three levels. The sheaf theorem supplies the objects, the subobject classifier supplies an internal notion of truth, and exponentials supply an internal function space. Lawvere–Tierney topologies describe controlled changes of truth or sheafification. Giraud’s principle is the recognition theorem: it tells when an abstract category has enough structure to behave like a category of sheaves.

Source for these results: [1].

5. Applications

Objects, morphisms, sheaves, and internal logic provide a generalized setting in which geometry and truth can vary together.

- (a) Algebraic geometry
- (b) sheaf cohomology
- (c) logic
- (d) constructive mathematics
- (e) category theory
- (f) type theory
- (g) and theoretical computer science.

6. Connections

Using existing theories

- (a) Category theory supplies objects, arrows, and universal constructions, while sheaves attach local data to a space and specify how that data restricts and glues.
- (b) Internal logic allows the topos itself to determine what counts as a truth value, and algebraic geometry supplies sites whose covers reflect arithmetic rather than ordinary open sets.
- (c) Type theory gives a computational reading of the same logical structure [1, 2].

Helping other theories

- (a) Topos theory helps cohomology because sheaf data can be resolved and its failure to glue can be measured.
- (b) It helps constructive mathematics by providing a setting where excluded middle need not hold, and helps computer science by interpreting types, programs, and proofs in a common semantics.

- (c) Homotopy-theoretic topoi extend this idea by treating equivalent proofs or paths as geometric data rather than identifying everything strictly [1, 3].
- (d) **Temporal logic and software verification.** In computer science, a program’s execution over discrete time steps can be modeled as a G -set where $G = \mathbb{Z}$ acts by shifting one step forward. The topos of $\mathbb{Z}$ -sets provides an internal logic in which propositions such as “eventually P holds” are interpreted by quantifying over the orbit of a state under the $\mathbb{Z}$ -action. Model-checking tools for linear temporal logic (LTL) exploit this connection: the truth value of a temporal formula at a state is determined by the entire forward orbit, which is exactly a G -set morphism into the subobject classifier of $\mathbf{Set}^{\mathbb{Z}}$ [1, 3].
- (e) **Type theory and proof assistants.** The Curry–Howard correspondence identifies types with propositions and programs with proofs. An elementary topos provides a model of dependent type theory: function types correspond to exponential objects, product types to categorical products, and the unit type to the terminal object. Proof assistants such as Coq and Agda are based on type theories whose semantics can be interpreted in topoi, ensuring that a verified program is correct not only syntactically but also in a rich mathematical universe [2, 3].

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1. Why is the category of sets a topos?** It has products, function sets, a one-element terminal set, and the two-element set classifying subsets.
- (b) **Exercise 2. Why may excluded middle fail in a topos?** Truth can be local and may not be decidable globally. The internal logic therefore need not prove P or $\text{not-}P$ for every proposition.

- (c) **Exercise 3. What does a subobject classifier do?** It turns the inclusion of a subset-like object into a characteristic map to a universal truth-value object.
- (d) **Exercise 4. Why are sheaves useful for arithmetic?** Grothendieck topologies create covers suited to algebraic varieties over finite fields, enabling étale and ℓ -adic cohomology.
- (e) **Exercise 5. What is a topos of G -sets?** Its objects are sets with a G -action and its arrows are equivariant maps, so group symmetry is present in the universe itself.

Chapter 88

Transcendental number theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. Which numbers are not roots of any nonzero polynomial with rational coefficients, and how can we prove that fact?

Formal

Transcendental number theory studies numbers beyond algebraic equations. It proves transcendence, algebraic independence, and quantitative lower bounds for polynomial expressions and linear forms in logarithms.

2. History

Historical development

- (a) **Definitions and history.**

An algebraic number is a root of a nonzero polynomial with rational coefficients. A number that is not algebraic is transcendental. A set is algebraically independent over a field when no nonzero polynomial relation with coefficients in that field holds among its members [1].

Liouville constructed transcendental numbers in the nineteenth century and proved that algebraic numbers cannot be approximated too well by rationals. Cantor showed that algebraic numbers are countable while real numbers are uncountable, so almost every real number is transcendental, although proving a particular constant transcendental can be very difficult [2].

3. Theory

Core theory

380. Major theorems.

Liouville's theorem says that an algebraic number of degree $d \geq 2$ cannot satisfy

$$\left| \alpha - \frac{p}{q} \right| < \frac{1}{q^{d+\epsilon}}$$

for infinitely many rationals p/q . Thus a number with exceptionally good rational approximations is transcendental.

The Lindemann–Weierstrass theorem implies that π is transcendental: if $i\pi$ were algebraic and nonzero, then $e^{i\pi}$ would be transcendental, contradicting $e^{i\pi} = -1$. The Gelfond–Schneider theorem says that if a is algebraic and not 0 or 1, and b is irrational algebraic, then every value of a^b is transcendental. Hence $2^{\sqrt{2}}$ and e^π are transcendental [3].

Alan Baker developed powerful lower bounds for linear forms in logarithms of algebraic numbers. These results solve or bound many Diophantine equations and give effective transcendence measures [4].

381. Open problems and methods.

The theory asks whether constants such as Euler's constant, zeta values, and many combinations of logarithms are rational, algebraic, or transcendental. Auxiliary functions, Diophantine approximation,

interpolation determinants, and height estimates are common tools. Algebraic independence is much harder than individual transcendence.

4. Important theorems and results

- (a) **Liouville criterion.** Exceptionally good rational approximation can force transcendence.
- (b) **Lindemann–Weierstrass theorem.** Linear independence of distinct algebraic exponents implies strong transcendence results for exponentials.
- (c) **Gelfond–Schneider theorem.** Algebraic $a \neq 0, 1$ raised to an irrational algebraic power is transcendental.
- (d) **Baker’s theorem.** Nonzero linear forms in logarithms of algebraic numbers have explicit lower bounds.
- (e) **Cantor’s cardinality result.** Almost all real numbers are transcendental because algebraic numbers are countable.

The results give increasingly strong ways to prove that a number is not algebraic. Liouville supplies an approximation test, Lindemann–Weierstrass controls exponentials, Gelfond–Schneider treats algebraic powers, and Baker gives quantitative lower bounds for logarithmic expressions. Cantor’s argument proves abundance rather than identifying a particular number: it shows that algebraic numbers form a countable exceptional set inside the uncountable real line.

Source for these results: [1].

5. Applications

Algebraic independence, Diophantine approximation, and lower bounds for logarithmic forms distinguish numbers beyond polynomial equations.

- (a) Number theory
- (b) Diophantine approximation

- (c) special constants
- (d) exponential equations
- (e) cryptography
- (f) and arithmetic geometry.

6. Connections

Using existing theories

- (a) Number theory supplies algebraic numbers and polynomial equations, while complex analysis studies exponential and logarithmic functions that cannot be captured by polynomial identities.
- (b) Diophantine approximation measures how closely a number can be approached by rationals or algebraic numbers, and heights measure the arithmetic complexity of those approximants.
- (c) Lower bounds for linear forms in logarithms then prevent an equation from having infinitely many unexpectedly close solutions [1, 4].

Helping other theories

- (a) The theory helps exponential Diophantine equations by proving that expressions such as powers and logarithms cannot cancel too accurately.
- (b) It helps arithmetic geometry bound rational points on curves and distinguish algebraic from transcendental parameters.
- (c) Results about constants such as e and π also explain why certain exact numerical coincidences cannot arise from polynomial relations with rational coefficients [1, 2].

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1. Why is every rational number algebraic?**
The rational number p/q is a root of $qx - p = 0$.
- (b) **Exercise 2. Why is $\sqrt{2}$ algebraic but not rational?** It is a root of $x^2 - 2$, so algebraic; the parity proof shows no rational number squares to 2.
- (c) **Exercise 3. Why is π transcendental?** Lindemann's theorem implies that if a nonzero algebraic number α is used in e^α , the result cannot be the required algebraic value of $e^{i\pi} = -1$ when $\alpha = i\pi$ is assumed algebraic.
- (d) **Exercise 4. Why does countability not identify a particular transcendental number?** It proves that almost all reals are transcendental, but a randomly described real may not have a proof attached to its identity.
- (e) **Exercise 5. What does algebraic independence mean for two numbers?** It means no nonzero polynomial $P(x, y)$ with coefficients in the base field satisfies $P(\alpha, \beta) = 0$.

Chapter 89

Twistor theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. Can spacetime geometry and quantum fields be represented more naturally by complex geometric data than by points and coordinates in spacetime?

Formal

Twistor theory, proposed by Roger Penrose, treats complex twistor space as a fundamental arena from which spacetime and fields can be recovered.

2. History

Historical development

(a) Origin and basic space.

Roger Penrose proposed twistor theory in 1967, influenced by Ivor Robinson's null congruences and by developments in relativity and complex analysis. Projective twistor space is $\mathbb{CP}^3$, while non-projective twistor space is a four-dimensional

complex vector space with a Hermitian form of signature $(2, 2)$ [1].

Twistor coordinates combine spinor information. The conformal group of compactified Minkowski space acts naturally on twistor space. A spacetime point corresponds to a projective line in twistor space, allowing spacetime fields to be encoded as complex-geometric objects [2].

3. Theory

Core theory

382. The Penrose transform.

Holomorphic functions and cohomology classes on twistor space correspond to solutions of massless field equations in spacetime. Contour integrals recover fields from twistor data. Penrose's nonlinear graviton construction represents self-dual solutions of Einstein's equations by deformations of complex structure. Ward's construction represents self-dual Yang–Mills fields using holomorphic vector bundles [3].

383. Concrete illustration: the Penrose transform in flat $\mathbb{R}^4$.

Consider flat Minkowski space $\mathbb{R}^4$ with coordinates (t, x, y, z) and the associated projective twistor space $\mathbb{PT} \cong \mathbb{CP}^3$. A point $p \in \mathbb{R}^4$ determines a projective line $\mathbb{CP}^1 \subset \mathbb{PT}$ via the incidence relation $Z^\alpha = p_{a\dot{a}}\pi^{a\dot{a}}$ in spinor notation. Suppose one prescribes a holomorphic function $f(Z)$ on an open region of $\mathbb{PT}$. The Penrose transform recovers a field $\phi(x)$ on $\mathbb{R}^4$ by integrating f over the $\mathbb{CP}^1$ corresponding to each spacetime point:

$$\phi(x) = \oint_{\mathbb{CP}_x^1} f(Z) \omega,$$

where ω is the natural holomorphic 1-form on the twistor line. The output ϕ automatically satisfies the massless wave equation $\square\phi = 0$. In this flat-space example the computation is concrete: pick $f(Z) = Z^0/(Z^1 Z^2)$ on a suitable domain, perform the contour integral parametrizing the $\mathbb{CP}^1$ by the spinor ratio π^1/π^0 , and read off the resulting solution $\phi(t, x, y, z)$ on spacetime. The PDE has been solved entirely by complex integration on twistor space.

384. **Scattering amplitudes.**

Twistor methods reorganized calculations in gauge theory. MHV formulas, twistor actions, BCFW recursion, Grassmannian integrals, and the amplituhedron express scattering amplitudes in geometric forms. Witten's twistor string theory linked perturbative Yang–Mills amplitudes with strings in twistor space [4].

385. **A plain-language picture.**

In ordinary spacetime, a light ray is described by where it is and which direction it travels. Twistor theory changes the bookkeeping: it treats the light-ray direction and its conformal information as the primary data. A single spacetime event is then represented by the family of light rays that pass through it. In projective twistor space that family is a line. The word line is therefore not a claim that spacetime is one-dimensional; it is a compact way to store all null directions through one event [1, 2].

Worked conceptual example. Suppose a massless field is known on twistor space as a holomorphic function or cohomology class. The Penrose transform integrates that data along the projective line associated with each spacetime point. The output is a field on spacetime satisfying the relevant massless wave equation. The difficult differential equation has been replaced by a holomorphic-data problem, and the transform explains how to return to the physical field [3].

4. Important theorems and results

- (a) **Penrose transform.** Cohomology classes of suitable holomorphic twistor data correspond to massless fields in spacetime.
- (b) **Incidence correspondence.** A spacetime point corresponds to a projective line in twistor space.
- (c) **Nonlinear graviton theorem.** Self-dual conformal geometry can be reconstructed from appropriate complex deformations of twistor space.
- (d) **Ward construction.** Self-dual Yang–Mills fields correspond to holomorphic bundle data.

- (e) **BCFW recursion.** Scattering amplitudes can be built recursively from lower-point amplitudes.

The incidence correspondence changes the basic object: a spacetime point becomes a line in twistor space. The Penrose transform then turns holomorphic data on those lines into solutions of field equations. The nonlinear graviton and Ward constructions extend this idea to self-dual gravity and gauge fields, while BCFW recursion shows how related geometric and analytic structures can simplify amplitude calculations. These results require complex-analytic and self-dual hypotheses; they do not describe every spacetime or every field theory.

Source for these results: [1].

5. Applications

Spinors, complex geometry, and incidence relations recast spacetime and field equations in conformal variables.

- (a) General relativity
- (b) quantum field theory
- (c) scattering amplitudes
- (d) integrable systems
- (e) and differential geometry.

6. Connections

Using existing theories

- (a) Twistor theory replaces spacetime points by geometric data describing null directions, so complex geometry and spinors encode the causal structure of relativity.
- (b) Sheaf cohomology turns holomorphic data on twistor space into fields on spacetime, while representation theory organizes the spin and symmetry labels.

- (c) Differential equations become statements about holomorphic bundles or cohomology classes, which can be easier to solve and transform back [1, 2].

Helping other theories

- (a) The transform helps construct self-dual solutions of relativity and gauge theory because a nonlinear spacetime equation becomes a bundle-gluing problem.
- (b) In integrable systems it exposes hidden complex geometry, and in scattering amplitudes it makes factorization and recursion visible.
- (c) These are not separate tricks: the same incidence relation translates spacetime propagation into holomorphic geometry [3, 4, 5].
- (d) **Computer vision.** Twistor-theoretic ideas enter computer vision through the study of the space of camera motions. The group of Euclidean motions $SE(3)$ acts on images, and its geometry can be described using a spinorial or twistorial parameterization. The incidence between light rays and image planes is structurally identical to the twistor incidence relation. Recent work on camera networks and multi-view geometry uses twistor-inspired representations to simplify the reconstruction of 3D scenes from 2D images, particularly when the camera calibration is unknown.
- (e) **Medical imaging and MRI reconstruction.** In MRI, data are collected in k -space (Fourier space) rather than directly in image space. The reconstruction problem—recovering the image from Fourier samples—is an inverse problem with geometric structure. Twistor methods have been applied to accelerate compressed-sensing MRI by exploiting the Penrose transform: instead of solving the reconstruction PDE in image space, one works with the simpler holomorphic representation on twistor space and transforms back. This approach can reduce the number of required samples and improve reconstruction quality for diffusion MRI, where the signal is naturally a solution of a massless equation on a curved background.

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1. What is a twistor?** It is a point of a complex vector or projective space carrying spinor and conformal information.
- (b) **Exercise 2. Why does a spacetime point become a line?** Incidence relations between spacetime coordinates and twistor spinors define a projective family associated with the point.
- (c) **Exercise 3. What does the Penrose transform accomplish?** It converts holomorphic or cohomological data on twistor space into solutions of massless differential equations.
- (d) **Exercise 4. Why are self-dual fields important?** Self-duality reduces nonlinear equations to integrable geometric structures while retaining rich examples.
- (e) **Exercise 5. What is the practical gain for amplitudes?** Twistor geometry exposes factorization and recursion, turning long diagram calculations into compact geometric formulas.

Chapter 90

Type theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. How can a formal system prevent ill-formed constructions by recording what kind of object every expression is?

Formal

Type theory classifies terms by types. Its rules say which terms may be formed, how they compute, and what counts as equality. Through Curry–Howard, types correspond to propositions and terms to proofs or programs.

2. History

Historical development

(a) Origin and history.

Bertrand Russell developed type hierarchies to avoid paradoxes such as the set of all sets that do not contain themselves. Church’s simply typed lambda calculus connected types with

functions. Per Martin-Lof developed intuitionistic type theory as a foundation for constructive mathematics. Calculus of constructions underlies proof assistants such as Coq and Lean [1].

3. Theory

Core theory

386. Terms, types, and rules.

A judgment may be written $\Gamma \vdash t : T$, meaning that under assumptions Γ , term t has type T . Function types, product types, sum types, dependent products, and dependent sums are built by formation, introduction, elimination, and computation rules.

The type $A \rightarrow B$ is a function from A to B . The product $A \times B$ is a pair. The sum $A + B$ records a choice between alternatives. A dependent product $\Pi x : A. P(x)$ expresses a statement for every x , while a dependent sum $\Sigma x : A. P(x)$ packages a witness and evidence [2].

387. Logic and computation.

Under Curry–Howard, a proof of $A \rightarrow B$ is a function that turns a proof of A into a proof of B . A proof of $A \times B$ is a pair of proofs. A term reduces by computation rules, so a proof can carry an executable witness. Intuitionistic type theory does not automatically include the law of excluded middle, which makes it constructive.

Dependent types let the type of an expression depend on a value. A vector type can record its length, allowing the type checker to reject an out-of-bounds operation before execution. This is why type theory is central to verified programming and proof assistants [3].

388. Homotopy and category theory.

Homotopy type theory interprets types as spaces, terms as points, and equalities as paths. Univalence treats equivalent types as equal in a controlled sense. Cubical type theory gives computational models of these ideas. Cartesian closed categories model simply

typed lambda calculus, while locally cartesian closed categories model dependent type theory [4].

4. Important theorems and results

- (a) **Curry–Howard correspondence.** Propositions are types, proofs are terms, and proof normalization is computation.
- (b) **Strong normalization.** In important typed calculi, every reduction sequence terminates.
- (c) **Progress and preservation.** Well-typed programs do not get stuck: they either are values or can take a step, and their types remain unchanged.
- (d) **Dependent-type correspondence.** Dependent products model universal quantification and dependent sums model existential quantification.
- (e) **Church–Rosser theorem.** If a term reduces in two ways, the resulting terms can be further reduced to a common result in confluent systems.
- (f) **Univalence principle.** In homotopy type theory, equivalences between types give paths witnessing equality of types.

Source for these results: [1].

5. Applications

Typing judgments, dependent types, and normalization connect proofs with programs whose terms can be checked mechanically.

- (a) Programming languages
- (b) proof assistants
- (c) constructive mathematics
- (d) formal logic
- (e) category theory
- (f) linguistics
- (g) and homotopy theory.

6. Connections

Using existing theories

- (a) Logic supplies propositions and inference, while the lambda calculus supplies functions as executable expressions.
- (b) A type records what kind of term a program or proof is allowed to be, so type checking catches an invalid application before it runs.
- (c) Proof theory explains normalization, category theory explains composition and universal structure, and computation gives the correspondence between constructing a term and carrying out an algorithm [1, 2].

Helping other theories

- (a) Type theory supports programming languages because a compiler can reject a term whose types do not fit, and it supports proof assistants because a checked proof is a typed term.
- (b) Dependent types let the type mention a value, such as the length of a vector, so the checker can verify that an operation preserves a specification.
- (c) Homotopy type theory extends the same idea by treating paths between objects as mathematical structure [1, 4].

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1. What is the type of the identity function?**
If $x : A$, then $\lambda x.x$ has type $A \rightarrow A$.
- (b) **Exercise 2. What does a product type represent?**
A term of $A \times B$ contains both an A -term and a B -term, analogous to a proof of A and B .

- (c) **Exercise 3. Why are dependent types useful for arrays?**
The type can include the length, so concatenation and indexing rules can be checked statically.
- (d) **Exercise 4. What is the empty type?** It has no terms. A function from it to any type is valid because no input exists that could violate the rule.
- (e) **Exercise 5. Why can type theory formalize mathematics?** Its rules can encode numbers, sets, functions, proofs, and constructions while the checker verifies every term.

Chapter 91

Wheel theory

1. Overview

Intuitive

Begin with the problem, not the notation. Ask what objects the theory studies, what change or operation is allowed, and what feature the theory tries to keep reliable. Can algebra make division total, including division by zero, without silently pretending ordinary inverse laws still hold?

Formal

A wheel is an algebraic structure in which division is always defined. It extends a commutative ring or semiring with an inverse-like operation and a special value for $0/0$.

2. History

Historical development

(a) Motivation and history.

In ordinary arithmetic, a/b is undefined when $b = 0$. Computer systems may need every operation to return a value. Jesper Carlstrom developed the theory of wheels in the early 2000s [1].

The name comes from viewing the real projective line as a circle and adding a bottom point representing $0/0$. A complex projective line is a sphere; adding the extra point gives a related geometric picture.

3. Theory

Core theory

389. Definition and changed rules.

A wheel has a set, constants 0 and 1, commutative associative addition and multiplication, and a unary operation written $/x$. Division is shorthand for $x/y = x \cdot (/y)$. The inverse operation is involutive:

$$//x = x.$$

It is multiplicative, and additional axioms modify familiar distributive rules so that expressions remain defined when a denominator is zero.

In a wheel, x/x need not equal 1, and $0x$ need not equal 0 in the general case. These changes prevent illegal cancellation from turning $0/0$ into an ordinary number. The special value $0/0$ behaves like a bottom element [2].

390. Uses and interpretation.

Wheels provide a total algebraic data type for rational expressions. A computer algebra system can manipulate an expression without repeatedly checking whether a denominator vanishes; the result records the exceptional value instead of losing it. A wheel agrees with ordinary arithmetic where denominators are nonzero.

391. A worked example.

Consider the expression

$$\frac{x^2 - 1}{x - 1}.$$

For an ordinary number with $x \neq 1$, factoring gives

$$\frac{(x - 1)(x + 1)}{x - 1} = x + 1.$$

At $x = 1$, the original expression is $0/0$, while the shortened expression has value 2. Ordinary algebra must therefore remember the condition $x \neq 1$; cancelling first and substituting later changes the question.

A wheel keeps the exceptional value visible. The original expression is assigned the wheel's value for $0/0$, while the expression $x + 1$ remains equal to 2 at $x = 1$. The two expressions agree where cancellation is legal, but they are not silently declared equal everywhere. This is the practical benefit of totalized arithmetic: a symbolic program can continue its calculation without confusing an exceptional value with an ordinary number [1, 2].

4. Important theorems and results

- (a) **Total division.** Every pair x, y has a defined quotient x/y .
- (b) **Involution.** Applying the inverse operation twice returns the original element.
- (c) **Extension principle.** A commutative ring or semiring can be extended to a wheel under suitable constructions.
- (d) **Projective model.** The real projective line with an added bottom point gives the geometric picture behind a real wheel.
- (e) **Modified cancellation.** Identities such as $x/x = 1$ are restricted because they fail at exceptional values.

The results describe how a wheel extends ordinary arithmetic while retaining a total division operation. Involution supplies the inverse-like structure, and the extension principle embeds familiar rings or semirings into the wider system. Modified cancellation is essential: division is always defined, but ordinary field identities cannot be applied at exceptional values without checking the wheel's rules.

Source for these results: [1].

5. Applications

Totalized division and changed algebraic identities provide a consistent setting in which division remains a defined operation at

zero.

- (a) Universal algebra
- (b) computer algebra
- (c) formal specification
- (d) and division by zero.

6. Connections

Using existing theories

- (a) Universal algebra asks which equations an operation must satisfy, while rings and semirings provide the ordinary addition and multiplication that a wheel extends.
- (b) The key change is to make division total: instead of leaving $1/0$ undefined, the structure assigns it an explicit value and records which familiar cancellation laws must be weakened.
- (c) Formal specification is needed because software must know exactly how exceptional values propagate [1, 2].

Helping other theories

- (a) Wheel theory helps computer algebra systems manipulate expressions without stopping whenever an intermediate denominator becomes zero.
- (b) A symbolic program can carry the exceptional value through addition, multiplication, and inversion, then report the result under the wheel's rules.
- (c) The connection is useful for formal verification because every expression has a defined denotation, but ordinary field identities may not be used unless their nonzero assumptions have been checked [1, 3].

7. Sample Questions

Exercise reference: [1]. The cited edition is the source for the exercise set; consult its Exercises section for the official statement and numbering.

- (a) **Exercise 1. What is a/b in a wheel?** It is shorthand for $a \cdot (/b)$ and is defined even if $b = 0$.
- (b) **Exercise 2. Why can $0/0$ not simply be 1?** That would make ordinary cancellation inconsistent with division. A wheel assigns a special value and changes the identities that would cause the contradiction.
- (c) **Exercise 3. What happens when $b \neq 0$?** In a wheel extending the real numbers, the quotient agrees with the ordinary real quotient.
- (d) **Exercise 4. Why is the inverse operation unary?** Division is defined by multiplying by the inverse-like value of the denominator.
- (e) **Exercise 5. What problem does a total operation solve in software?** It prevents undefined intermediate expressions from crashing symbolic manipulation; exceptional results remain explicit values.

Part II

Worked modules: learning by doing

The entries above are a map. The modules in this part are the book's actual lessons. Each begins with a small problem, makes the hidden assumptions visible, and ends with exercises. Try the exercises before reading the answer; explaining a result in your own words is more valuable than memorizing a definition.

Chapter 92

A few examples before the modules

Example 1: probability and a medical test

Suppose 1 person in 100 has a condition. A test correctly detects 99 out of 100 affected people, but falsely reports “positive” for 5 out of 100 healthy people. In 10,000 people, about 100 are affected and 99 of them test positive. Of the 9,900 healthy people, about 495 also test positive. Therefore only $99/(99 + 495) = 1/6$ of the positive results are expected to be genuine. The lesson is not that the test is useless; it is that accuracy and the background rate must be considered together.

Example 2: graph theory and a cheap network

Four houses lie at the corners of a square. Roads along the four sides each cost 1 unit, while a diagonal road costs 1.5 units. The diagonal gives a faster route between two houses, but it is not needed to connect all four. A network designer who wants the cheapest connected system chooses the four sides, costing 4 units; a designer who values speed may add the diagonal, costing 5.5 units. Graph theory separates the questions “Can everyone reach everyone?” and “What is the shortest route?”

Example 3: coding theory and a flipped bit

Send the four messages 00, 01, 10, and 11 as 000000, 010101, 101010, and 111111. If one bit flips during transmission, the receiver can compare the received string with the four valid strings and choose the closest one. For instance, 010001 is closest to 010101, so the receiver restores 01. The price is extra data: six transmitted bits carry only two message bits. Reliability is purchased with redundancy.

Example 4: group theory and a clock

On a twelve-hour clock, adding 5 hours and then adding 9 hours gives the same result as adding 14 hours, which is the same as adding 2 hours. The action “add 5” has an inverse: “add 7,” because together they add 12 and return to the starting hour. Clock arithmetic is a small example of a group, where actions can be combined, doing nothing is allowed, and every action can be undone.

Example 5: topology and holes

A circle drawn on paper has one loop that cannot shrink to a point without leaving the circle. A filled disk has no such hole. Stretching the circle into an oval does not change this fact, but filling it in does. Topology ignores the exact measurements and records the feature that survives bending: the presence or absence of a hole.

Example 6: number theory and remainders

To find the remainder of 3^{10} after division by 7, calculate the short cycle: $3^1 = 3$, $3^2 = 2$, $3^3 = 6$, $3^4 = 4$, $3^5 = 5$, and $3^6 = 1$ modulo 7. The cycle repeats every six powers, and 10 leaves remainder 4 after division by 6. Therefore 3^{10} has the same remainder as 3^4 , namely 4. Large calculations become manageable because remainders repeat.

Important theorems and results

- (a) **Bayes' rule.** It explains the medical-test calculation by combining a prior rate with test evidence.
- (b) **Spanning-tree principle.** It explains why a connected network can be built without unnecessary cycles.
- (c) **Minimum-distance decoding.** It explains why redundancy can identify and correct sufficiently few transmission errors.
- (d) **Group axioms.** They explain why clock operations can be composed, reversed, and treated as symmetries.
- (e) **Homotopy invariance.** It explains why continuous deformation preserves the broad topological features in the example.
- (f) **Fermat's little theorem.** It explains why modular powers can repeat under a prime modulus.

Chapter 93

Module 1: Probability

Imagine a bus that arrives every ten minutes, but you reach the stop at a random time. If you have no timetable, your waiting time is anywhere from zero to ten minutes. The average wait is five minutes, not ten: you arrive at a typical point inside the interval.

Probability begins by listing possible outcomes and assigning weights to them. An event is simply a collection of outcomes. The rules are bookkeeping: the chance of an impossible event is zero, the chance of certainty is one, and the chance of either of two non-overlapping events is the sum of their chances. Conditional probability answers a different question: after learning that a person tested positive, how likely is illness? The answer depends not only on the test's accuracy but also on how common the illness was before testing.

Worked example. Suppose 1 in 100 people has a condition. A test catches 99 in 100 affected people but falsely flags 5 in 100 unaffected people. In a group of 10,000, about 100 are affected and 99 test positive. Of the 9,900 unaffected people, about 495 also test positive. So among positive results, roughly $99/(99 + 495) = 1/6$ are genuine. The test can be good while a positive result is not certainty.

Exercises. (1) Why does doubling the number of tests not automatically double certainty? (2) What extra information would make the example more reliable? *Answers:* (1) The base rate and false positives still matter. (2) A representative population and an independently measured test performance.

Important theorems and results

- (a) **Bayes' rule.** For events with positive conditioning probability, $P(A | B) = P(B | A)P(A)/P(B)$. It combines a prior rate with the evidence supplied by a test.

Chapter 94

Module 2: Statistics

Statistics starts with a boundary: we see a sample, not the whole world. A survey of 1,000 voters is not the election; a trial of 500 patients is not every patient. A statistic is useful only when we say how it was collected and how uncertain the conclusion is.

The mean is sensitive to extreme values, while the median is the middle observation after sorting. A confidence interval is a method for producing a range that would capture the target at a stated rate under repeated use; it is not a guarantee that one particular interval contains the truth. A hypothesis test asks whether the observed result would be unusual under a chosen baseline. It cannot by itself prove a cause, and a small probability under the baseline is not the probability that the baseline is false.

Worked example. A new teaching method raises a class average from 68 to 72. We compare it with another class, measure spread, check whether students were assigned fairly, and report the range of plausible improvements. If the new class was already stronger, the four-point difference may not be caused by the method. Design is as important as calculation.

Exercises. (1) Give one reason a large sample can still mislead. (2) Why use a comparison group? *Answers:* (1) It can be biased or measured badly. (2) To estimate what would have happened without the intervention.

Important theorems and results

- (a) **Central limit theorem.** Under suitable assumptions, standardized sums of many observations approach a normal distribution. The approximation supports uncertainty intervals, but it does not repair biased sampling or poor measurement.
- (b) **Gauss–Markov theorem.** In a correctly specified linear model with the usual assumptions, least squares has the smallest variance among linear unbiased estimators.

Chapter 95

Module 3: Graph theory

Draw dots for objects and lines for relationships. The dots may be towns, people, computers, or tasks; the lines may be roads, friendships, cables, or dependencies. A route is a sequence of joined dots. A connected network lets every place reach every other; a bridge is a connection whose removal breaks that property.

The important move is to forget irrelevant detail. A road map becomes a graph when only connectivity matters; a weighted graph keeps lengths or costs on the lines. A shortest-path method repeatedly improves the best known route. A spanning tree connects every dot using no unnecessary loop, useful when building a cheap network. Coloring assigns labels so joined dots differ, useful when conflicting activities cannot share a time slot.

Worked example. Four towns form a square, with one diagonal. If each road costs one unit, the diagonal shortens one pair's trip but is not needed to connect all towns. Removing it leaves a cycle; removing any one square side still leaves another route. The graph makes redundancy visible.

Exercises. (1) What changes when roads receive different costs? (2) Why might a network designer keep a loop? *Answers:* (1) Fewest roads and cheapest route may differ. (2) A loop provides an alternative route when one link fails.

Important theorems and results

- (a) **Handshaking lemma.** The sum of the degrees of all vertices equals twice the number of edges. Consequently, every finite graph has an even number of odd-degree vertices.
- (b) **Spanning-tree result.** Every connected finite graph contains a spanning tree, and a minimum spanning tree gives a connected network of minimum total edge cost.

- [2] R. Diestel, *Graph Theory*, Springer, 2017.

Chapter 96

Module 4: Information and coding

Information theory asks how much uncertainty a message removes. A predictable symbol carries little new information; an unexpected symbol carries more. Compression works by replacing repeated or predictable patterns with shorter descriptions. It cannot make truly random data shorter on average without losing information.

Coding theory addresses the opposite danger: noise. Add redundancy in a pattern that makes likely errors recognizable. A simple parity check can detect an odd number of flipped bits. A stronger code can locate and correct errors because valid messages are deliberately spaced apart in the space of all possible strings.

Worked example. To send one of four symbols, use 00, 01, 10, or 11. If one bit may flip, use 000000, 010101, 101010, and 111111. The messages are far apart, so a received string with one error can be assigned to the nearest valid message. The cost is three times as many transmitted bits.

Exercises. (1) Why can redundancy improve reliability? (2) Why not add unlimited redundancy? *Answers:* (1) It leaves clues about the intended message. (2) It consumes bandwidth, storage, time, and energy.

Important theorems and results

- (a) **Source-coding theorem.** For a memoryless source, reliable lossless compression cannot have average length below the entropy in the long run, while suitable codes can approach that bound.
- (b) **Distance bound.** A code with minimum Hamming distance d detects at least $d - 1$ errors and corrects at least $\lfloor (d - 1)/2 \rfloor$ errors.

Chapter 97

Module 5: Group theory

Take a square. Rotating it by a quarter turn, half turn, or three-quarter turn, and flipping it in four ways, gives eight symmetries. Doing one after another gives another symmetry; doing nothing changes nothing; every move can be undone. These simple facts are the heart of a group.

The theory asks which features of an object are preserved by its symmetries and how complicated actions can be built from a few basic ones. A group need not be a collection of physical motions: rearranging a list, adding clock hours, or changing coordinates can have the same pattern of composition and reversal.

Worked example. On a clock, adding 5 hours and then 9 hours is the same as adding 14 hours, which is the same as adding 2 hours. The arithmetic wraps around after 12. This small group models repeating schedules and modular arithmetic used in cryptography.

Exercises. (1) What is the inverse of adding 5 on a 12-hour clock? (2) Why is order important for some symmetries? *Answers:* (1) Adding 7. (2) Rotating then flipping a shape can differ from flipping then rotating.

Important theorems and results

- (a) **Lagrange's theorem.** The order of a finite subgroup divides the order of its finite ambient group. It turns a symmetry calculation into a divisibility test.

Chapter 98

Module 6: Topology

Topology studies what survives a continuous deformation. A rubber band can become a circle, but it cannot become two separate bands without being cut. A mug and a doughnut each have one tunnel, so topology treats them as the same broad kind of object; a sphere has none.

The basic features are connected pieces and holes of different kinds. A loop around a hole may fail to shrink to a point. Homology packages counts of such holes into algebraic summaries, while homotopy studies continuous deformations of paths and maps. These tools are powerful because a noisy drawing can change its exact lengths without changing its broad structure.

Worked example. A road network can be viewed as a one-dimensional shape. A closed alternative route is a loop. If a new road fills the loop by connecting every point across a region, the network's cycle structure changes. This is why topology can help analyze sensor and transportation networks.

Exercises. (1) Is a square topologically different from a circle? (2) What operation changes a mug's number of holes? *Answers:* (1) No, if edges are allowed to bend and corners are not important. (2) Cutting, gluing, or drilling a hole.

Important theorems and results

- (a) **Homotopy invariance.** Continuous maps that can be deformed into one another induce the same map on homology.

Therefore homology records features that survive continuous deformation.

Chapter 99

Module 7: Calculus and dynamical systems

A derivative measures an instantaneous rate: the speedometer reports how position changes at this moment. An integral adds many small contributions: distance can be recovered by adding small pieces of speed over time. A differential equation says how a quantity changes and asks what history follows from that rule.

Dynamical systems theory studies that history as a whole. It asks whether a system settles, cycles, escapes, or becomes highly sensitive to its starting point. A model may be deterministic while prediction is limited because measurements are never infinitely precise.

Worked example. If a population grows by 10 percent each year, its next value is 1.1 times its current value. Repeating the rule gives exponential growth. If resources limit growth, the growth rate falls as the population approaches a carrying level, producing a different long-term story. The equation expresses an assumption; data must test it.

Exercises. (1) What does a zero derivative mean at an instant? (2) Why can two close starting values later differ greatly? *Answers:* (1) No instantaneous change. (2) The system may amplify small differences, as in chaos.

Important theorems and results

- (a) **Fundamental theorem of calculus.** Differentiation and integration are inverse operations under the usual continuity assumptions.
- (b) **Linearization principle.** Near a nondegenerate equilibrium, the eigenvalues of the linearized system determine local stability; zero real parts require further analysis.

Chapter 100

Module 8: Number theory

Whole numbers cannot be smoothly adjusted: divisibility either works or it does not. Prime numbers are the basic building blocks because every positive whole number factors into primes in only one way apart from order. Congruence arithmetic keeps only remainders, which is why clock arithmetic is a useful model.

Worked example. To compute a large power modulo 7, reduce after each multiplication. The powers of 3 cycle: 3, 2, 6, 4, 5, 1. The cycle makes enormous calculations manageable. Public-key cryptography uses related facts: multiplying two secret primes is easy, while recovering them from their product can be difficult for suitably large numbers.

Exercises. (1) What is 17 modulo 5? (2) Why are primes useful for building secret keys? *Answers:* (1) 2. (2) Their multiplication is easy to perform but reversing it can be computationally hard.

Important theorems and results

- (a) **Fundamental theorem of arithmetic.** Every integer greater than one has a factorization into primes that is unique up to order.
- (b) **Fermat's little theorem.** If p is prime and p does not divide a , then $a^{p-1} \equiv 1 \pmod{p}$. This explains the repeating powers

used in the example.

Chapter 101

Module 9: Approximation

A complicated function can be replaced locally by a line or more accurately by a polynomial. The replacement is valuable only when we know where it works and how far it may be from the original. This is the difference between a controlled approximation and a guess.

Worked example. Near zero, $\sin x$ is close to x when x is measured in radians. At $x = 0.1$, this is a good shortcut; at $x = 2$, it is not. Adding the next correction, $-x^3/6$, improves the estimate. A numerical method should report both its answer and a reason to trust its accuracy.

Exercises. (1) Why does an approximation need a range of validity? (2) What is the danger of adding more terms blindly? *Answers:* (1) Errors can grow away from the region where the estimate was built. (2) A series may not converge or rounding errors may dominate.

Important theorems and results

- (a) **Taylor's theorem.** A smooth function equals its Taylor polynomial plus a remainder controlled by a higher derivative. The remainder is what turns a numerical guess into an error-bounded approximation.
- (b) **Weierstrass approximation theorem.** Every continuous real-valued function on a closed bounded interval can be uniformly approximated by polynomials.

- [2] E. W. Cheney, *Introduction to Approximation Theory*, AMS Chelsea, 1982.

Chapter 102

Module 10: Computation and proof

An algorithm is a finite recipe. Automata theory studies machines with restricted memory; computation theory asks what any algorithm can do; proof theory studies formal chains of reasons. These are different questions: a problem can be solvable in principle but too slow in practice, or a statement can be true without a particular formal system being able to prove it.

Worked example. A spelling checker can recognize whether a word follows a finite list of allowed patterns. It cannot, using only that finite memory, remember an arbitrary number of opening parentheses and match them all. A stack adds the needed memory. The model explains why different programming tasks require different resources.

Exercises. (1) What does an algorithm require that a vague wish does not? (2) Why is “not yet computed” different from “cannot be computed”? *Answers:* (1) Explicit, repeatable steps. (2) More time may solve the first; no algorithm can solve the second.

Important theorems and results

- (a) **Halting theorem.** No algorithm can correctly decide for every program and input whether that program eventually halts.

- (b) **Cook–Levin theorem.** Boolean satisfiability is NP-complete, making it a central comparison problem for computational difficulty.

References

- [2] D. J. Velleman, *How to Prove It*, Cambridge University Press, 2019.

Chapter 103

Module 11: Game, queue, and control theory

Game theory studies decisions whose results depend on other decision-makers. Queue theory studies congestion caused by random arrivals and limited service. Control theory studies feedback: measuring a system, comparing it with a target, and correcting it. All three ask how local choices affect a changing whole.

Worked example. Two hospitals can each either share beds with the other or reserve them. Sharing helps patients when demand differs, but each hospital may prefer to reserve beds during a shortage. A model lists choices and payoffs, then asks whether cooperation is stable. If arrivals are uncertain, queue calculations show the cost of waiting; feedback can redirect ambulances as capacity changes.

Exercises. (1) Why can a locally sensible choice harm a network? (2) What makes feedback unstable? *Answers:* (1) Other agents and congestion react to it. (2) Corrections may be too large, too late, or based on noisy measurements.

Important theorems and results

- (a) **Nash's existence theorem.** Every finite game has at least one mixed-strategy Nash equilibrium.

- (b) **Little's law.** In a stable long-run queue, the average number in the system equals the arrival rate multiplied by the average time spent in the system.
- (c) **Feedback stability.** A feedback controller is useful only when the closed-loop dynamics remain stable; increasing gain can reduce error in one regime and cause oscillation or divergence in another.

Chapter 104

Module 12: Algebraic geometry

An equation such as $x^2 + y^2 = 1$ describes a shape: a circle. Changing the equation changes the shape, and changing the number system changes which points count. Algebraic geometry studies this two-way relationship between formulas and their solution sets.

The algebra is useful because a shape may be hard to draw but easy to describe through the operations on its coordinates. Ideals collect equations that vanish on the same set; elimination removes unwanted coordinates; schemes extend the viewpoint to arithmetic questions involving primes and finite number systems. These advanced tools are not magic new shapes: they are ways to remember local information that an ordinary picture loses.

Worked example. The equations $x + y = 3$ and $x - y = 1$ describe two lines. Adding them removes y and gives $2x = 4$, so $x = 2$ and then $y = 1$. Elimination theory generalizes this small act to many polynomial equations and many variables.

Exercises. (1) What does a solution point mean geometrically? (2) Why eliminate a variable? *Answers:* (1) It is a point satisfying every equation. (2) To find a condition or projection involving only the quantities of interest.

Important theorems and results

- (a) **Hilbert's Nullstellensatz.** Over an algebraically closed field, polynomial equations and radical ideals describe the same affine solution sets.
- (b) **Bézout's theorem.** Projective plane curves with no common component meet in a number of points counted with multiplicity equal to the product of their degrees.

Theory dependency and application map

This table summarises the relationships explained in the individual chapters. The dependency column names the background ideas needed to begin studying a theory; the final column names theories that reuse its methods or results. These are relationships, not strict prerequisites: advanced mathematics is interconnected, and a course may introduce the subjects in a different order.

Theory name	Depends on	Helps other theories
Algebraic geometry	algebra, topology, calculus, and the geometric objects introduced in the chapter	its constructions support topology, number theory, representation theory, and mathematical physics
Almgren–Pitts min–max theory	sets, continuity, topology, and geometric intuition	its invariants support homology, homotopy, geometry, dynamical systems, data analysis, and manifold theory
Approximation theory	calculus, limits, linear algebra, and real or complex analysis	its analytic tools support differential equations, probability, physics, numerical computation, and statistics

Theory name	Depends on	Helps other theories
Arakelov theory	integer arithmetic, algebra, and proof; advanced chapters also require fields or complex analysis	its arithmetic tools support cryptography, algebraic geometry, coding theory, and arithmetic statistics
Asymptotic theory	calculus, limits, linear algebra, and real or complex analysis	its analytic tools support differential equations, probability, physics, numerical computation, and statistics
Automata theory	sets, functions, and the chapter's own definitions	its objects and methods are reused by neighbouring areas of mathematics and applications
Bass–Serre theory	sets, functions, algebra, and proof; the chapter then introduces its own operations and axioms	its structures support representation theory, algebraic geometry, number theory, coding, topology, logic, and computer science
Bifurcation theory	calculus, differential equations, linear algebra, and phase-plane reasoning	its ideas support chaos, ergodic theory, control, mathematical biology, and physics
Braid theory	sets, functions, algebra, and proof; the chapter then introduces its own operations and axioms	its structures support representation theory, algebraic geometry, number theory, coding, topology, logic, and computer science
Brill–Noether theory	algebra, topology, calculus, and the geometric objects introduced in the chapter	its constructions support topology, number theory, representation theory, and mathematical physics

Theory name	Depends on	Helps other theories
Catastrophe theory	calculus, differential equations, linear algebra, and phase-plane reasoning	its ideas support chaos, ergodic theory, control, mathematical biology, and physics
Category theory	sets, functions, algebra, and proof; the chapter then introduces its own operations and axioms	its structures support representation theory, algebraic geometry, number theory, coding, topology, logic, and computer science
Chaos theory	calculus, differential equations, linear algebra, and phase-plane reasoning	its ideas support chaos, ergodic theory, control, mathematical biology, and physics
Character theory	sets, functions, algebra, and proof; the chapter then introduces its own operations and axioms	its structures support representation theory, algebraic geometry, number theory, coding, topology, logic, and computer science
Choquet theory	sets, functions, and the chapter's own definitions	its objects and methods are reused by neighbouring areas of mathematics and applications
Class field theory	sets, functions, algebra, and proof; the chapter then introduces its own operations and axioms	its structures support representation theory, algebraic geometry, number theory, coding, topology, logic, and computer science
Cobordism theory	sets, continuity, topology, and geometric intuition	its invariants support homology, homotopy, geometry, dynamical systems, data analysis, and manifold theory

Theory name	Depends on	Helps other theories
Coding theory	probability, linear algebra, calculus, and mathematical modelling	its models support statistics, engineering, information theory, optimization, economics, and scientific prediction
Cohomology theory	sets, continuity, topology, and geometric intuition	its invariants support homology, homotopy, geometry, dynamical systems, data analysis, and manifold theory
Continuum theory	sets, continuity, topology, and geometric intuition	its invariants support homology, homotopy, geometry, dynamical systems, data analysis, and manifold theory
Control theory	probability, linear algebra, calculus, and mathematical modelling	its models support statistics, engineering, information theory, optimization, economics, and scientific prediction
Deformation theory	algebra, topology, calculus, and the geometric objects introduced in the chapter	its constructions support topology, number theory, representation theory, and mathematical physics
Dempster–Shafer theory	probability, linear algebra, calculus, and mathematical modelling	its models support statistics, engineering, information theory, optimization, economics, and scientific prediction
Dimension theory	sets, continuity, topology, and geometric intuition	its invariants support homology, homotopy, geometry, dynamical systems, data analysis, and manifold theory

Theory name	Depends on	Helps other theories
Distribution theory	calculus, limits, linear algebra, and real or complex analysis	its analytic tools support differential equations, probability, physics, numerical computation, and statistics
Dynamical systems theory	calculus, differential equations, linear algebra, and phase-plane reasoning	its ideas support chaos, ergodic theory, control, mathematical biology, and physics
Elimination theory	algebra, topology, calculus, and the geometric objects introduced in the chapter	its constructions support topology, number theory, representation theory, and mathematical physics
Ergodic theory	sets, functions, and the chapter's own definitions	its objects and methods are reused by neighbouring areas of mathematics and applications
Extremal graph theory	sets, counting, combinatorics, and algorithms	its network and counting methods support optimization, probability, computer science, and network science
Field theory	sets, functions, algebra, and proof; the chapter then introduces its own operations and axioms	its structures support representation theory, algebraic geometry, number theory, coding, topology, logic, and computer science
Galois theory	sets, functions, algebra, and proof; the chapter then introduces its own operations and axioms	its structures support representation theory, algebraic geometry, number theory, coding, topology, logic, and computer science

Theory name	Depends on	Helps other theories
Game theory	probability, linear algebra, calculus, and mathematical modelling	its models support statistics, engineering, information theory, optimization, economics, and scientific prediction
Graph theory	sets, counting, combinatorics, and algorithms	its network and counting methods support optimization, probability, computer science, and network science
Group theory	sets, functions, algebra, and proof; the chapter then introduces its own operations and axioms	its structures support representation theory, algebraic geometry, number theory, coding, topology, logic, and computer science
Hodge theory	algebra, topology, calculus, and the geometric objects introduced in the chapter	its constructions support topology, number theory, representation theory, and mathematical physics
Homology theory	sets, continuity, topology, and geometric intuition	its invariants support homology, homotopy, geometry, dynamical systems, data analysis, and manifold theory
Homotopy theory	sets, continuity, topology, and geometric intuition	its invariants support homology, homotopy, geometry, dynamical systems, data analysis, and manifold theory

Theory name	Depends on	Helps other theories
Ideal theory	sets, functions, algebra, and proof; the chapter then introduces its own operations and axioms	its structures support representation theory, algebraic geometry, number theory, coding, topology, logic, and computer science
Index theory	sets, continuity, topology, and geometric intuition	its invariants support homology, homotopy, geometry, dynamical systems, data analysis, and manifold theory
Information theory	probability, linear algebra, calculus, and mathematical modelling	its models support statistics, engineering, information theory, optimization, economics, and scientific prediction
Intersection theory	algebra, topology, calculus, and the geometric objects introduced in the chapter	its constructions support topology, number theory, representation theory, and mathematical physics
Invariant theory	sets, functions, algebra, and proof; the chapter then introduces its own operations and axioms	its structures support representation theory, algebraic geometry, number theory, coding, topology, logic, and computer science
Iwasawa theory	integer arithmetic, algebra, and proof; advanced chapters also require fields or complex analysis	its arithmetic tools support cryptography, algebraic geometry, coding theory, and arithmetic statistics
K-theory	sets, functions, and the chapter's own definitions	its objects and methods are reused by neighbouring areas of mathematics and applications

Theory name	Depends on	Helps other theories
Knot theory	sets, continuity, topology, and geometric intuition	its invariants support homology, homotopy, geometry, dynamical systems, data analysis, and manifold theory
L-theory	sets, functions, and the chapter's own definitions	its objects and methods are reused by neighbouring areas of mathematics and applications
Lattice theory	sets, functions, algebra, and proof; the chapter then introduces its own operations and axioms	its structures support representation theory, algebraic geometry, number theory, coding, topology, logic, and computer science
Lie theory	sets, functions, algebra, and proof; the chapter then introduces its own operations and axioms	its structures support representation theory, algebraic geometry, number theory, coding, topology, logic, and computer science
M-theory	algebra, topology, calculus, and the geometric objects introduced in the chapter	its constructions support topology, number theory, representation theory, and mathematical physics
Measure theory	calculus, limits, linear algebra, and real or complex analysis	its analytic tools support differential equations, probability, physics, numerical computation, and statistics

Theory name	Depends on	Helps other theories
Model theory	sets, functions, algebra, and proof; the chapter then introduces its own operations and axioms	its structures support representation theory, algebraic geometry, number theory, coding, topology, logic, and computer science
Module theory	sets, functions, algebra, and proof; the chapter then introduces its own operations and axioms	its structures support representation theory, algebraic geometry, number theory, coding, topology, logic, and computer science
Morse theory	sets, continuity, topology, and geometric intuition	its invariants support homology, homotopy, geometry, dynamical systems, data analysis, and manifold theory
Nevanlinna theory	calculus, limits, linear algebra, and real or complex analysis	its analytic tools support differential equations, probability, physics, numerical computation, and statistics
Number theory	integer arithmetic, algebra, and proof; advanced chapters also require fields or complex analysis	its arithmetic tools support cryptography, algebraic geometry, coding theory, and arithmetic statistics
Obstruction theory	sets, continuity, topology, and geometric intuition	its invariants support homology, homotopy, geometry, dynamical systems, data analysis, and manifold theory
Operator theory	calculus, limits, linear algebra, and real or complex analysis	its analytic tools support differential equations, probability, physics, numerical computation, and statistics

Theory name	Depends on	Helps other theories
Order theory	sets, functions, algebra, and proof; the chapter then introduces its own operations and axioms	its structures support representation theory, algebraic geometry, number theory, coding, topology, logic, and computer science
Percolation theory	probability, linear algebra, calculus, and mathematical modelling	its models support statistics, engineering, information theory, optimization, economics, and scientific prediction
Perturbation theory	calculus, limits, linear algebra, and real or complex analysis	its analytic tools support differential equations, probability, physics, numerical computation, and statistics
Probability theory	probability, linear algebra, calculus, and mathematical modelling	its models support statistics, engineering, information theory, optimization, economics, and scientific prediction
Proof theory	sets, functions, algebra, and proof; the chapter then introduces its own operations and axioms	its structures support representation theory, algebraic geometry, number theory, coding, topology, logic, and computer science
Queue theory	probability, linear algebra, calculus, and mathematical modelling	its models support statistics, engineering, information theory, optimization, economics, and scientific prediction

Theory name	Depends on	Helps other theories
Ramsey theory	sets, counting, combinatorics, and algorithms	its network and counting methods support optimization, probability, computer science, and network science
Random matrix theory	probability, linear algebra, calculus, and mathematical modelling	its models support statistics, engineering, information theory, optimization, economics, and scientific prediction
Representation theory	sets, functions, algebra, and proof; the chapter then introduces its own operations and axioms	its structures support representation theory, algebraic geometry, number theory, coding, topology, logic, and computer science
Ring theory	sets, functions, algebra, and proof; the chapter then introduces its own operations and axioms	its structures support representation theory, algebraic geometry, number theory, coding, topology, logic, and computer science
Scheme theory	sets, functions, algebra, and proof; the chapter then introduces its own operations and axioms	its structures support representation theory, algebraic geometry, number theory, coding, topology, logic, and computer science
Semigroup theory	sets, functions, algebra, and proof; the chapter then introduces its own operations and axioms	its structures support representation theory, algebraic geometry, number theory, coding, topology, logic, and computer science

Theory name	Depends on	Helps other theories
Set theory	sets, functions, algebra, and proof; the chapter then introduces its own operations and axioms	its structures support representation theory, algebraic geometry, number theory, coding, topology, logic, and computer science
Shape theory	sets, continuity, topology, and geometric intuition	its invariants support homology, homotopy, geometry, dynamical systems, data analysis, and manifold theory
Sheaf theory	sets, functions, algebra, and proof; the chapter then introduces its own operations and axioms	its structures support representation theory, algebraic geometry, number theory, coding, topology, logic, and computer science
Sieve theory	integer arithmetic, algebra, and proof; advanced chapters also require fields or complex analysis	its arithmetic tools support cryptography, algebraic geometry, coding theory, and arithmetic statistics
Singularity theory	algebra, topology, calculus, and the geometric objects introduced in the chapter	its constructions support topology, number theory, representation theory, and mathematical physics
Soliton theory	calculus, limits, linear algebra, and real or complex analysis	its analytic tools support differential equations, probability, physics, numerical computation, and statistics
Spectral theory	calculus, limits, linear algebra, and real or complex analysis	its analytic tools support differential equations, probability, physics, numerical computation, and statistics

Theory name	Depends on	Helps other theories
String theory	sets, functions, algebra, and proof; the chapter then introduces its own operations and axioms	its structures support representation theory, algebraic geometry, number theory, coding, topology, logic, and computer science
Sturm–Liouville theory	calculus, limits, linear algebra, and real or complex analysis	its analytic tools support differential equations, probability, physics, numerical computation, and statistics
Surgery theory	sets, continuity, topology, and geometric intuition	its invariants support homology, homotopy, geometry, dynamical systems, data analysis, and manifold theory
Teichmüller theory	sets, continuity, topology, and geometric intuition	its invariants support homology, homotopy, geometry, dynamical systems, data analysis, and manifold theory
Theory of computation	sets, functions, and the chapter's own definitions	its objects and methods are reused by neighbouring areas of mathematics and applications
Theory of equations	sets, functions, and the chapter's own definitions	its objects and methods are reused by neighbouring areas of mathematics and applications
Theory of statistics	probability, linear algebra, calculus, and mathematical modelling	its models support statistics, engineering, information theory, optimization, economics, and scientific prediction

Theory name	Depends on	Helps other theories
Topology	sets, continuity, topology, and geometric intuition	its invariants support homology, homotopy, geometry, dynamical systems, data analysis, and manifold theory
Topos theory	sets, functions, algebra, and proof; the chapter then introduces its own operations and axioms	its structures support representation theory, algebraic geometry, number theory, coding, topology, logic, and computer science
Transcendental number theory	integer arithmetic, algebra, and proof; advanced chapters also require fields or complex analysis	its arithmetic tools support cryptography, algebraic geometry, coding theory, and arithmetic statistics
Twistor theory	algebra, topology, calculus, and the geometric objects introduced in the chapter	its constructions support topology, number theory, representation theory, and mathematical physics
Type theory	sets, functions, algebra, and proof; the chapter then introduces its own operations and axioms	its structures support representation theory, algebraic geometry, number theory, coding, topology, logic, and computer science
Wheel theory	sets, functions, algebra, and proof; the chapter then introduces its own operations and axioms	its structures support representation theory, algebraic geometry, number theory, coding, topology, logic, and computer science

References

The map summarizes the dependencies and applications explained in the chapters; the individual chapter bibliographies provide the subject-specific sources.

The student's toolbox: difficult words made ordinary

This short dictionary is meant to be used while reading. The point is not to avoid precise ideas, but to give each precise idea a familiar handle.

Algebra	A way of writing rules for combining and changing quantities or objects. It is not limited to school equations.
Algorithm	A recipe that always says what step to take next, such as the instructions for sorting a list.
Continuous	Changing without a sudden jump or tear, like moving a cup across a table.
Dimension	How many independent directions are needed to move around an object. A line has one, a sheet two, and a room three.
Equation	A statement that two descriptions have the same value. Solving it means finding the situations where that statement is true.
Function	A dependable input-to-output rule. A temperature converter and a vending machine are everyday examples.
Geometry	The study of shape, position, distance, and motion.

Group	A collection of reversible actions that can be performed one after another. Rotations of a cube are a model example.
Limit	The value a process gets closer and closer to, even if it never arrives there in a finite number of steps.
Matrix	A rectangular table of numbers used to record many inputs and outputs at once.
Model	A simplified description built to answer a particular question. Every model leaves something out.
Operator	A rule that acts on another object, often a function or a list of numbers.
Proof	A chain of small, checkable reasons that forces a conclusion to be true under stated rules.
Set	A collection of objects considered together. The objects can be numbers, places, choices, or other collections.
Symmetry	A change that leaves the important appearance or structure unchanged.
Topology	The study of features that survive bending and stretching, such as connected pieces and holes.
Vector	A quantity with several components, often used to describe a direction, a position, or a list of measurements.
Wheel	An algebraic system designed to let division by zero be written as a total operation, with special rules that prevent it from behaving like ordinary field arithmetic.

How to study a theory without getting lost

For each chapter, make a four-line note in your own words:

- (a) Draw or describe the real object: a queue, a knot, a message, a vibrating string, or a set of choices.
- (b) Name the change that matters: noise, motion, uncertainty, growth, symmetry, or competition.
- (c) Say what the theory measures or preserves. This is usually the heart of the subject.
- (d) Write one decision it improves: decode, predict, classify, schedule, control, compare, or prove impossible.

Then explain the theory to another person without using its name. If the explanation still works, you understand the idea rather than merely recognizing the vocabulary. Only after that should you return to the equations or formal definitions in a textbook.

A map of the connections

The theories are easier to remember as families. *Probability* describes uncertainty, while *statistics* learns from observations of that uncertainty. *Graph theory* describes connections, while *queue theory*, *game theory*, and *control theory* use connections to study waiting, competition, and correction. *Topology* asks which features survive bending; *geometry* keeps measurements too; *algebra* records operations and symmetry. *Information theory* asks how messages can be represented, and *coding theory* makes them survive noise. *Number theory* studies whole-number structure, while algebraic geometry joins equations to shapes.

The same pattern appears again and again: choose a simple representation, find a feature that remains reliable, and use it to make a prediction. That is the common thread tying this very large list together.

Where to go next

This book is a first conversation, not a credential. The following standard references are reliable next steps; a student should use the one matching their preparation rather than trying to read them all.

Elementary foundations

Courant and Robbins, *What Is Mathematics?*;
Ian Stewart, *Concepts of Modern Mathematics*.

Proof and discrete mathematics

Daniel Velleman, *How to Prove It*; Richard Johnsonbaugh, *Discrete Mathematics*.

Probability and statistics

David Williams, *Weighing the Odds*; David Freedman, Robert Pisani, and Roger Purves, *Statistics*.

Calculus and differential equations

Michael Spivak, *Calculus*; Walter Strauss, *Partial Differential Equations*.

Algebra and number theory

Joseph Gallian, *Contemporary Abstract Algebra*; G. H. Hardy and E. M. Wright, *An Introduction to the Theory of Numbers*.

Topology and geometry

Sidney Morris, *Topology Without Tears*; James Munkres, *Topology*.

Computation and information

Michael Sipser, *Introduction to the Theory of Computation*; Thomas Cover and Joy Thomas, *Elements of Information Theory*.

Advanced subjects

Serge Lang, *Algebra*; Robin Hartshorne, *Algebraic Geometry*; John Lee, *Introduction to Smooth Manifolds*. These are reference texts, not assumed prerequisites for this book.

The source list is useful for names, but it is not a textbook and should not be treated as an authority for every application sentence. In a classroom or publication, each advanced chapter should be checked against a specialist reference before being used as course material.

A final thought

The theories in this book do not form a ladder from “easy” to “hard.” They form a network. A graph can describe a symmetry; probability can live on a measure space; topology can guide an algorithm; algebra can decode a message. Mathematics becomes powerful when one viewpoint is carried into another place.

The recurring habit is simple: identify what may change, identify what must remain, and choose a language that makes the invariant visible. That is why theories made for apparently abstract questions so often return in phones, bridges, medicines, software, and the night sky.

Scope note and source

The chapter titles follow the list at https://en.wikipedia.org/wiki/List_of_mathematical_theories, which is available under the Creative Commons Attribution–ShareAlike 4.0 License. The explanations and examples in this manuscript are original popular expositions; they are not copied from the linked article. Because mathematical fields overlap, several chapters naturally point to one another.
